205008

Nature

A WEEKLY

ILLUSTRATED JOURNAL OF SCIENCE

VOLUME XXIX

NOVEMBER 1883 to APRIL 1884

> *"To the solid ground*
> *Of Nature trusts the mind which builds for aye."*—WORDSWORTH

London and New York
MACMILLAN AND CO.
1884

LONDON:
R. CLAY, SONS, AND TAYLOR, PRINTERS
BREAD STREET HILL, E.C.

INDEX

Abbadie (A. d'), the Remarkable Sunsets, 132
Abney (Capt., F.R.S.), Wave-lengths of A, *a*, and Lines in Infra-red of Visible Spectrum, 190
Abyssinia, Dr. Stecker's Travels in, 347
Achard's Continuous Electric Brake, 245
Affinity, Chemical, Oswald's Studies of, 391; Flavitsky's Theory of, 392
Africa: Exploration of Stanley's Congo Expedition, 15; Portuguese Expedition to West, 64, 245; Dr. Holub's Expedition, 135, 346; Russian Expedition to West, 296; Dr. Emin-Bey's Explorations, 160; Dr. Richard Böhm's and P. Reichardt's Explorations, 272; Races of Western Tropical, H. H. Johnston, 303; Junker's Expedition, 318; O'Neill's Explorations, 346; Dr. Chavanne's Expedition, 346; Sketch of the Modern Languages of Africa, Robt. Needham Cust, Prof. A. H. Keane, 377; Geology of Central Africa, H. Drummond, 551; African Spiders, 408; Dr. Junker's Discoveries in the Wellé Region, 584
Agardh (Dr.), on Algæ, Mary P. Merrifield, 340
Agassiz (Prof. Alex.), Embryological Monographs, 16; the Porpitidæ and Velellidæ, 262
Agates, Prof. M. Forster Heddle, 419
Agriculture, an American Rothamsted, Prof. W. Fream, 238
Agriculture in Sussex, 575
Agricultural Society, Royal, Journal of, 75
Air, Velocity of Sound in, D. J. Blaikley, 148
Air, Dusty, on the Formation of Small Clear Spaces in, John Aitken, 322; Phenomena exhibited by, in the Neighbourhood of Strongly-Illuminated Bodies, Profs. Oliver J. Lodge and J. W. Clark, 417
Air-Wave, the Krakatoa, General Strachey, F.R.S., 181
Air-Waves, Earthquakes and, General Strachey, F.R.S., and Maxwell Hall, 427
Airy (Sir G. B., F.R.S.), on Chepstow Railway Bridge, 75
Aitken (John), on the Formation of Small Clear Spaces in Dusty Air, 322
Alaska: Zoology and Botany ot, 362; the Volcanic Eruption of Mount St. Augustin, Geo. Davidson, 441
Albany (Duke of), Death of, 534
Alexander (Thos.), Protection by Mimicry—a Problem in Mathematical Zoology, 405
Alexeyeff's Theory of Solutions, 391
Alfta, Remarkable Meteor and Aurora at, 159
Algæ, Drs. Agardh and Rabenhorst on, Mary P. Merrifield, 340
Algeria, Sinking of Earth at Bona, 460
Algiers, Earthquake in, 415
Almanac, the Nautical, 89
Alpine Clubs, German, 462; Austrian, 462; French, 488
Alps of New Zealand, Green's, Prof. Bonney, F.R.S., 281
Aluminium, Peculiar Absorption of Iodic Acid by, Dr. G. Gore, F.R.S., 254
Amambara Creek, Flegel's Map of, 585
Amazons (Upper Regions), Topography and Ethnography of, Colini, 272
America: Co-education of the Sexes in, 158; November Meeting of National Academy of Sciences, 161; Clifford Richardson on American Wheat, Prof. J. Wrightson, 173; American Geology, F. V. Hayden, A. Geikie, F.R.S., 233; an American Rothamsted, Prof. W. Fream, 238; American Naturalist, 165, 375; American Journal of Science, 141, 252, 397, 466, 540, 613; American Association for the Advancement of Science, 87; Recent Low Temperatures in America, Dr. John Rae, F.R.S., 287
Amu-Daria, Russian Explorers on the Old Bed of the, 416, 557
Amur, Changes of Level of, 15
Anatomy for Artists, John Marshall, 30, 56, 123
Anderson's Handbook of Archæological Collections in Indian Museum, 27; Guide to Calcutta Zoological Gardens, 426
Anemometer, a New, Prof. Börnstein, 280
Animal Body, Nuclein in, Prof. Kossel, 352
Animal Intelligence, J. M. Hayward, 357
Animals: Mental Evolution in, F. J. Faraday, 335, 381, 428; G. J. Romanes, F.R.S., 330, 336, 404, 428
Animals, Teaching, to Converse, Sir J. Lubbock, F.R.S., 216, 237, 547; Col. H. Stuart Wortley, 261
Annalen der Physik und Chemie, 94, 253, 276, 495
Annals of Mathematics (Magazine), 135
Annelida of the North Atlantic, 25
Anthropology: Anthropological Institute, 119, 166, 254, 303, 351, 446, 542; the Study of, Prof. Flower, F.R.S., 319, 388; Foundation of an Anthropological Society at Bordeaux, 389; Anthropological Society of Paris, 414; Anthropological Notes in Solomon Islands, Surgeon Guppy, 429; Anthropological Results of Dr. Finsch's Journey to the Pacific, 462; Erkert's Anthropological Measurements in Caucasus, 557; at the British Association Meeting at Montreal, 582
Aphides, British, G. B. Buckston, F.R.S., 288
Arabia, Geology of, Prof. T. G. Bonney, F.R.S., 350
Arabin Gums, C. O'Sullivan, 253

Archæological Collections of the Indian Museum, 27
Archibald (E. D.), the Remarkable Sunsets, 176
Archives, Italiennes, de Biologie, 23, 142
Archives of the Physical and Natural Sciences, Geneva, 277, 349
Arctic Expedition (*Dijmphna*), New, 88
Arctic Expedition, another attempt to rescue the Greely, 415
Argentine Republic, Splenic Fever in, Dr. Roy, 91
Argyll (the Duke of), the Unity of Nature, 474, 524
Aristotelian Society, 45
Arizona, Geological Survey of, H. M. Wilson, 272
Arlberg Tunnel, Completion of, 64, 87
Artists, Anatomy for, 30, 56, 123
Ascidiæ Compositæ, Classification of the, Prof. Herdman, 429
Ash (Volcanic), Analysis by Dr. Reusch of Krakatoa, 388
Ash of Grain grown at Rothamsted, Analysis of, Lawes and Gilbert, 445
Ashes (Volcanic), Analysis of Krakatoa, Renard, 134
Asia (Central), Dr. Regal's Explorations in, 416
Asia Minor, Earthquakes in, 437
Asian Explorations, Dr. Riebeck's, 417
Asiatic Society of Bengal, Centenary of, 316
Association of German Naturalists and Physicians, 18
Association, Scientifique de France, 272
Astronomical Column, 45, 69, 88, 112, 135, 159, 185, 246, 273, 296, 345, 367, 390, 415, 536, 558, 606
Astronomische Gesellschaft, 558
Astronomical Station on Pic du Midi, Studies made for establishment of permanent, MM. Thollon and Trépied, 7
Atlantic (North), Norwegian Expedition: Zoology, 25
Atlantic Soundings, 188
Atlantic, Relative Level of Mediterranean and, Tillo and Bourdalou, 185
Atlantic, Greatest Depth of, 319
Atmosphere, the Upper Currents of the, 154
Atmosphere of China, Dust, Prof. J. P. O'Reilly, 260
Atomic Weight of Tellurium, Brauner, 391
Atomic Weights, Redeterminations of, 391
Atti dell' Accademia Reale dei Lincei, 47, 95, 443, 466, 565, 614
Attraction et Gravitation d'après Newton, Mme. Clémence Royer, 235
Audebert (J.), Wild Tribes of Madagascar, 347
Auricular Sensations, Subjective, Prof. Lucæ, 568
Aurora and Meteor at Alfta, 159
Aurora Borealis: Prof. Lemström's Observations of the, 111; on the Height of the, Adam Paulsen, 337; Measuring the, Dr. Sophus Tromholt, 409; in Iceland, Dr. Sophus Tromholt, 537
Austral Judgment, the, 49
Australia: Initiation Ceremonies, A.W. Howitt, 254; Geological Exploration in Western, E. T. Hardman, 294; Water in, F. T. Mott, 311; Exploration by Winnicke of unknown interior of, 346; Volcanic Eruption in Western, 388; Australian Observatories, 390
Austrian Polar Expedition, Results of, Lieut. Wohlgemuth, 246; Botanical Expedition to Azerbijan, 316
Austro-Hungary, Ornithological Observatories in, 246
Axioms of Geometry, Edward Geoghegan, 551; Prof. O. Henrici, F.R.S., 573
Azerbijan, Austrian Botanical Expedition to, 316

Bacas (Dario) Determinants, 378
Bacillus of Typhoid Fever, Prize offered for Essay on, 583
Backhouse (T. W.), Pons' Comet, 7; the Quadrantids, 104; the Remarkable Sunsets, 251
Bacteria, 559; Bicentenary of, Ferdinand Cohn, 154
Bacterioscopic Measurements of Neva Water, Dr. Pehl, 557
Bailey (Prof. W. W.), Sprengel on Fertilisation of Flowers, 171; Ravens in United States, 478
Baker (J. G.) Review of Tuber-bearing Solanums, 328
Balance, Delicate, Suggestions for facilitating the use of a, Lord Rayleigh, F.R.S., 91; Hughes' New Magnetic, 263
Balfour (Prof. J. Hutton) Death of, 365; Obituary Notice of, 385
Baltic Scientific Researches, Finnish Government Steamer for, 225
Bamboo in Transcaucasia, Proposed Cultivation of, Woeikoff, 184
Barlow (Capt.), Sea covered with Pumice, 488
Barlow (W.), Internal Symmetry of Crystals, 186, 205; Probable Nature of the Internal Symmetry of Crystals, 404
Barometer, the Ear a, Dr. W. H. Stone and Geo. Rayleigh Vicars, 356; C. V. Boys, 333
Barometrical Sympathy with Earthquakes, Dr. Hector, F.R.S., 87
Barometro Araucano, Baron Maclay, 303
Barrett (Prof. W. F.), on a Magnetic Sense, 476
Barrington (R. M.), the Remarkable Sunsets, 153; on the Absence of Earthworms from Canadian North-West Prairies, 237
Barytes from Chirbury, H. A. Miers, 29; C. J. Woodward, 77; H. A. Miers, 124
Bashforth (Rev. F.), On a Method of Estimating the Steadiness of Elongated Shot when Fired from Large Guns, 527
Bathymetrical Survey of Scottish Lochs, 487
Batteries, New Elements for Primary, Lalande and Chaperon, 227
Bead Ornaments of Palæolithic Man, Worthington G. Smith, 83
Beadon (Robert), the Remarkable Sunsets, 225
Bealby (J. P.), Java Eruption and Earthquake Waves, 30
Beardmore (N. B.), the Green Sun, 28
Becquerel (H.), Researches on Infra-red Rays of the Spectrum, 227
Beddard (F. E.), the New Prosector of the Zoological Society, 294
Bees, Habits of, Isabella Herschel, 104
Behm (Dr.), Death of, 487
Beketoff (Prof.), on Dr. Sachs' Theory of the Relations between the Increase and Segmentation of Cells in the Embryonal Parts of Plants, 461
Bengal Dyes and Tans, H. W. McCann, 147
Bengal Asiatic Society, Centenary of, 316
Bennett (A. W.), on the Reproduction of the Zygnemaceæ, 142
Ben Nevis Observatory, 14, 86, 134; a Christmas Visit to, Prof. G. Chrystal, 219; Ascent of, 9, 365; Weather on, T. Sington, 261; Meteorological Observations from, 342
Berghaus (Prof. H. K.), Death of, 437
Berlin: Cremation Society, 461; Physiological Society, 72, 144, 168, 255, 280, 352, 448, 543; Physical Society, 48, 168, 192, 279, 304, 400, 472, 498, 568; Geographical Society, 160
Berly's Electrical Directory, 524
Bermuda, Earthquake in, 15
Bernstein (Dr. R.), Death of, 415
Berwick-on-Tweed, Remarkable Meteor seen at, 272
Beryllium, Spectrum of, 90; Hartley on, 391
Beyerinck (Dr.), the Remarkable Sunsets, 175, 308
Bittleston (Lieut. G. H.), the Remarkable Sunsets, 152
Bias in Walking, Unconscious: G. H. Darwin; Thos. Hawksley, 286; Sara S. Owen, 336; Dr. J. Rae, F.R.S., 311, 384; W. G. Simpson, 356; Dr. Garson, 310; R. McLachlan, F.R.S., F. M. Campbell, Stephen A. Marshall, 311
Bibliography: Scientific, Quaritch's Catalogue, 212; Meteorological, C. J. Symons, F.R.S., 550
Bickmore's (Prof.), Lectures on Natural History to School Teachers, 184
Bicycles and Tricycles, C. V. Boys, 478
Biddulph (Sir R., C.B.), the Cedar Forests of Cyprus, 597
Bidwell (Shelford), on an Explanation of Hall's Phenomenon, 468
Biological Notes, 16
Biological Laboratory on the English Coast, a, 473
Biological Investigation of the British Coasts, Society for, 533
Birds, Towering of, Sir J. Fayrer, F.R.S., 55
Birds' Eggs, the Structure of, Prof. Tarkhanoff, 461
Birds of Japan, New List of, 604
Birmingham Philosophical Society, 254
Birvari, Earthquake at, 415
Bishop (S. E.), Remarkable Sunsets, 259, 549, 573
Blaikley (D. J.), Velocity of Sound in Air, 148
Blake (Jas.), on the Incubation Period of Scientific Links, 16
Blake (Prof. J. G.), Volcanic Group of St. David's, 303
Blakiston (Capt. T.), Protection by Mimicry—a Problem [illegible] Mathematical Zoology, 405; List of the Birds of Japan, [illegible]
Bleaching, Dyeing, and Calico Printing, John Gardner, 425

Bles (E. J.), the Remarkable Sunsets, 427
Blue Sun, a, E. Metzger, 252
Blyth (A. W.), Poisons, Dr. Thos. Stevenson, 451
Bock's (Carl) Siam, Prof. A. H. Keane, 258
Bogies, Mr. Ruskin's, Rev. W. Clement Ley, 353
Böhn's (Dr. R.) African Explorations, 272
Bolletino della Societa Italiana Geografica, 346
Bona, Subsidence of Naïba Mountain, near, 15
Bone Caves of Ojcow, Prof. Dr. F. Römer, 449
Bonney (Prof. F.R.S.), Geology of South Devon Coast, 119; Cambrian Conglomerates, 208; the Alps of New Zealand, W. S. Green, 281; Geology of Arabia, 350
Bordeaux, Foundation of Anthropological Society at, 389
Borgen (Prof.), Nordenskjöld's Theories in connection with his Greenland Expedition, 14
Borneo Commercial Development, 462
Börnstein (Prof.), a New Anemometer, 280
Bosnia, Earthquake in, 159
Boston (U.S.A.), Water-Supply, Contamination by Spongilla fluviatilis of, 391
Botanic Garden Board, Report of New Zealand, 206
Botanical Work in China, Chas. Ford, 134
Botanical Expedition to Azerbijan, Austrian, 316
Botanico-Physiological Station in North Sweden, Proposed, 225
Botany in India, Progress of, 111
Botany of Alaska, Zoology and, 362
Botany: Relations between the Increase and Segmentation of Cells in the Embryonal Parts of Plants, Prof. Beketoff on Dr. Sachs' Theory, 461
Botany, Economic, the Kew Museums of, 581
Bourdalou, Relative Level of Mediterranean and Atlantic, 185
Boulenger (G.A.), the Ophidian Genus Simotes, 149
Bournemouth Natural Science Society, 64
Bovey (Prof.), Applied Mechanics, A. R. Willis, 122
Bower (F. O.), Rhyncopetalus montanum, 230
Bows, Circular Cloud, E. H. L. Firmstone, 406
Boys (C. V.), the Ear a Barometer, 333; Bicycles and Tricycles, 478
Bozward (J. Ll.), the Remarkable Sunsets, 131, 178
Brain, Tourguénief's, 389
Brake, Achard's Continuous Electric, 245
Brauner (B.), the Remarkable Sunsets, 223
Brauner, Atomic Weight of Tellurium, 391
Brazil, Pale Sun in, 87
Bremen Geographical Journal, 161
Bremen, Geographical Society of, 535, 585
Breguet (M.), Death of, 14
Bridge, on Chepstow Railway, Sir G. B. Airy, F.R.S., 75
Brioschi (Prof. Francesco), Appointed President of the Academy of the Lincei, 582
British Association, Montreal Meeting, 435, 459; Arrangements for Section F, 534; Anthropology at, 582
British Islands, Origin of the Scenery of the, A. Geikie, F.R.S., 325, 347, 396, 419, 442
British Noblemen during last three Generations, Weights of, Fras. Galton, F.R.S., 266
Brodhurst (B. E.), the Remarkable Sunsets, 153
Bronn (Dr. H. G.), Klassen und Ordnungen des Thierreichs, 5
Brooks' Comet, W. T. Sampson, 335]
Brorsen's Comet, 88
Brounoff's Researches into Variations of Temperature in consequence of Cyclones, 414
Brown (E.), the Remarkable Sunsets, 132
Brown (Dr. J. C.), Finland: Its Forests and Forest Management, Prof. W. Fream, 101
Brown (Prof. W. G.), the Remarkable Sunsets, 309
Brown (Wm.), Instinct, 428
Browne (Walter R.), Science and Engineering, 57
Browne (Lennox), Voice, Song, and Speech, Dr. W. H. Stone, 570
Brugnone (Abbé), Death of, 436
Brussa, Earthquake near, 272
Bryce's Bill to secure Access to Mountains and Moorlands in Scotland, 487
Brydone-Jack (W.), the Remarkable Sunsets, 250
Buckston (G. B., F.R.S.), British Aphides, 288
Budde (Dr.), the Remarkable Sunsets, 177
Budge (E.), New Inscription of Nebuchadnezzar, 375
Buhla, Prehistoric Burial Ground near, 460
Buildings, Earthquakes and, Dr. A. Ernst, 595
Bulletin de la Société de Géographie, 160
Bulletin of the American Geographical Society, 161
Bulletin of the Belgian Royal Academy, 190
Bulletins de la Société d'Anthropologie de Paris, 277
Bulletin de l'Académie Impériale des Sciences de St. Pétersbourg, 422
Bulletin de la Société des Naturalistes de Moscou, 300
Bulletin de l'Académie Belgique, 142, 421, 466, 565
Bunge (Dr.), Lena Polar Meteorological Station, 318
Bunkofer (Prof. W.), Determinants, 378
Burder (George F.), Remarkable Sunsets, 251, 525
Burial Ground at Cobern, Discovery of Franconian, 246
Burial Ground at Buhla, Prehistoric, 460
Burnett Lectures, On Light, G. G. Stokes, Prof. P. G. Tait, 545
Burnham's (Mr.) Double-Star Measures, 409
Burton (F. M.), the Remarkable Sunsets, 225
Bushel of Corn, a (A. S. Wilson), Prof. Wrightson, 26
Busley (Carl), Die Schiffsmaschine, 426

Cable-Protection Convention, 487
Cadell (H. M.), Geognosy of the Harz Mountains, 303, 447
Calcutta Zoological Gardens, Guide to, 426
Callorhynchus antarcticus, on some Embryos of, T. J. Parker, 46
Cambrian Conglomerates, H. Hicks, M.D., and Prof. Bonney, F.R.S., 208
Cambridge: Fellowship Examinations, Independent Work at, 43; Natural Science at, Local Examinations, 63; Philosophical Society, 96, 143, 166, 357, 470, 543
Cameron (Donald), Meteors, 56, 123, 287
Campbell (Prof. Lewis), the Remarkable Sunsets, 196
Campbell (F. M), Unconscious Bias in Walking, 311
Canadian North-West Prairies, Absence of Earthworms from, R. M. Christy, 213; R. M. Barrington, 237; Timothy E. Wilcox, 486
Cannibalism among Cave-Dwellers, Prof. Nehring, 366
Canoe unearthed at Pulborough, 15
Cape Horn, Report of French Mission to, Dr. Hyades, 191
Carniola, Discovery by Prof. Linhart of Great Ice Cavern in, 296
Carpenter (W. Lant), Energy in Nature, 74; Science Teaching in Elementary Schools, 317
Carpineto-Romano, Meteorological Observatory, 556
Casey (J., F.R.S.), Sequel to the First Six Books of Euclid, 571
Cats, Heredity in, E. B. Poulton, 20; Deafness in White, 237, 312; a Colony of, Geo. Rayleigh Vicars, 551; Cats on the District Railway, E. de M. Malan, 573; Rooke Pennington, 596
Caucasus, Science in the, 488; Erkert's Anthropological Measurements in, 557; the Population of, 605
Cave-Dwellers, Cannibalism among, Prof. Nehring, 366
Cecil (Henry), the Remarkable Sunsets, 132, 334
Cedar Forest of Cyprus, Sir R. Biddulph, C.B., 597
Cell, Reynier's Maximum, 227
Ceratodus forsteri, Morton, 16
Cetacea, Evolution of the, S. V. Wood, 147; Prof. W. H. Flower, F.R.S., 170
Challenger (H.M.S.), Zoological Reports of Voyage of, vols. v. vi. vii., 1, 521; Zoological Reports, F. B. White, 29
Chapman (E., M.A.), Physiology in Oxford, 76
Chavanne (Dr.), Antwerp, 296; African Expedition, 346
Chemistry: Chemical Society, 76, 95, 231, 253, 302, 399, 445, 469, 541, 566, 591, 616; Chemical Notes, 391; Oswald's Studies of Chemical Affinity, 391; Flavitsky's Theory of Chemical Affinity, 392; Refracting Power of Solid Chemical Compounds, Kanonnikoff, 391; Thermal Chemistry, Julius Thomsen, M. M. P. Muir, 209; Ira Remsen's Principles of Theoretical Chemistry, 283; General Principles of Chemistry, M. M. P. Muir, 317
Chenery (Thomas) Death of, 364
Chepstow Railway Bridge, on, Sir G. B. Airy, F.R.S., 75
Chester, Proposed Museum for, 88

Chicago Observatory, 69
China, Botanical Work in, Chas. Ford, 134; Magnetic Dip in South China and Formosa, Dr. Doberck, 214; Dr. Fritsche's Explorations in, 416; Explorations of South-Western, 462; Dust Atmosphere of China, Prof. J. P. O'Reilly, 260; Chinese Meteorology, Dr. Doberck, 271; Green Sun in China, 436; Chinese Palæontology, Prof. R. K. Douglas, 551
Chios, Earthquake at, 88
Chirbury, Barytes from, H. A. Miers, 29, 124; C. J. Woodward, 77
Chlorophyll, Note on the Constitution of, Edw. Schunck, F.R.S., 277
Cholera Commission, Report of German, 365, 460
Chrystal (Prof. G.), A Christmas Visit to Ben Nevis Observatory, 219; Three Hundredth Anniversary of the Edinburgh University, 577
Christiania Society of Science, 472
Christy (R. M.), Absence of Earthworms from Canadian North-West Prairies, 213
Christy's Notes on Useful Plants, 488
Chukche Peninsula, Dr. Aurel Krause on the Inhabitants of, 161
Cincinnati, the Observatory, 558
Circle, the Division of the, Antoine d'Abbadie, 28
Circling to the Left in a Mist, W. Larden, 262
Circular Cloud Bows, E. H. L. Firmstone, 406
Circular Rainbow, J. A. Fleming, 310; J. M. White, 357; T. R. Maynard, 357; G. K. Gilbert, 451
Circumpolar Expedition, British, 63; Capt. Dawson, 247
City and Guilds of London Technical Institute, 534
Civil Engineers, Institution of, 43
Clark (J. E.), the Remarkable Sunsets, 131, 225, 286
Clark (Prof. J. W.) and Prof. Oliver J. Lodge on the Phenomena exhibited by Dusty Air in the Neighbourhood of strongly Illuminated Bodies, 417
Clarke (Dr. Hyde), Green Sunlight, 76; the Remarkable Sunsets, 152
Clark Cells, on the Absolute Electromotive Force of, Lord Rayleigh, F.R.S., 565
Cleeve (Prof.), the Earth "Samaria," 391
Clerkenwell Road, Palæolithic Implement found in, 15
Clifton (Prof.), Measurement of Curvature of Lenses, 143
Cloud Bows, Circular, E. H. L. Firmstone, 406
Cloud-glow after Sunset, Unusual, Hon. F. A. R. Russell, 55; J. J. Walker, 77
Clocks, Sudden Stoppage of, G. H. Kinahan, 105
Clock, New Normal, at Yale College Observatory, 604
Clockwork in Parcels, Scheme for Discovering, W. de Fonvielle, 437
Cobern, Discovery of Franconian Burial Ground at, 246
Coccidæ in New Zealand, Ravages of, 200
Co-education of the Sexes in America, 158
Cohn (Ferdinand), Bicentary of Bacteria, 154
Cohn's Beiträge zur Biologie des Pflanzen, 443
Cold in Smyrna, 345
Colini (Dr.), on Lucioli's Topography and Ethnography, 9
College, Firth, Proposed Technical Department in, 183
Colman (A. P.), Ice Volcanoes—Mountain Rainbow, 550
Colony of Cats, Geo. Rayleigh Vicars, 551
Colour-Blind, Experiments on Neutral Points in Spectrum of, Dr. Kœnig, 168
Colour-sensitiveness, Dr. Kœnig's Experiments on, 496
Colours, Photography of, Greenwood Pim, 470
Comet, Brooks', W. T. Sampson, 335; Comet, Brorsen's, 88; Comet, D'Arrest's, 70; Comet, Encke's, 159: Comet, Pons', T. W. Backhouse, 7, 45, 112, 185, 273, 296, 367; Drawings of, 460; Tempel's, 1873 II., 45, 70, 185; a Southern, 296, 606; Comet of 1664, 345; First Comet, 1798, 135; Great Comet, 1882, 135; Comet, 1884, 558
Composite Portraiture adapted to the Reduction of Meteorological and other Similar Observations, G. M. Whipple, 420
Conglomerates, Cambrian, Dr. Hicks and Prof. Bonney, F.R.S. 208
Congo Expedition, Stanley's, 15; Departure of Lieut. Wissmann on New Expedition to the, 87; Ethnological Expedition of Dr. Zintgraff to the, 416; the Congo, H. H. Johnston, Prof. A. H. Keane, 579
Conn (H. W.) and J. S. Kingsley, on the Embryology of the Teleosts, 16

Modern Languages of Africa, Sketch of, Robert Needham Cust, Prof. A. H. Keane, 377
Möbius (Prof. K.), Christian Conrad Sprengel, 406
Moncel (Count Du), Death of, 387; Obituary Notice of, 412
Monk Fish, the, 348
Moncreiff (Lord), Past Hundred Years' History of Edinburgh Royal Society, 368
Monte Video, Earthquakes in, 437
Montsouris Observatory, 437
Moon, a Green, 604; in Sweden, 366
Morgan, (C. Lloyd), Instinct, 370, 405; Geo. J. Romanes, F.R.S., 379
Moritzburg Collection of Deers' Horns, the, 307
Morocco, Captain Crema's Journey to, 462
Morton (Mr.), Ceratodus forsteri, 16
Moseley (Prof. H. N., F.R.S.), Prof. Aug. Weismann on Sexual Cells of Hydromedusæ, 114; Peripatus, 196
Motion of Projectiles, E. Ristori, 572
Mott (F. T.), Meteor, 120; Water in Australia, 311
Mouchez (Admiral), Proposed Removal of Paris Observatory, 374
Mountain Rainbows, Ice Volcanoes, A. P. Colman, 550
Movements of the Earth, the, J. Norman Lockyer, F.R.S., 65, 201
Müller (Dr. F.), C. C. Sprengel, 334
Müller (Dr. Hermann), Memorial to, 244
Müller (H. W., F.R.S.), Striking Distance of Electric Discharge, 325
Müller (Hugo, F.R.S.), Researches on the Electric Discharge, 349
Muir (M. M. P.), Julius Thomsen's Thermochemische Untersuchungen, 209; General Principles of Chemistry, 317
Muirhead (L. P.), Meteoric Dust, 494
Munk (Prof.) "Experimental" Epilepsy, 72; Absorption of Fat in Animal Body, 472

Murray (J.) and A. Renard, Volcanic Ashes and Cosmic Dust, 585
Muscles (Voluntary) of Larynx and Jaws, Experimental Proof of Prof. Munk's Theory of Cortical Area of, Dr. H. Krause, 168
Museum for Chester, Proposed, 88
Museums (Dresden), Reports of, 226
Music and Science, Dr. W. H. Stone, 198
Musica e una Scienza, La, Dr. Primo Crotti, 198
Mygale, Protopterus, and Scorpions, Prof. E. Ray Lankester, 54

Nachrichten of the Royal Society of Sciences and of the University of Göttingen, 277, 300, 375
Nagasaki, Catachthonic Observatory near, 413
Naïba Mountain near Bona, Subsidence of, 15
National Academy of Sciences (America), November Meeting of, 161
Natural History, Prof. Bickmore's Lectures to School Teachers on, 184
Natural History for Working Men, Rev. W. Tuckwell, 344
Natural History Museum, South Kensington, 556
Natural Science at Cambridge Local Examinations, 63
Nature, Unity of, Duke of Argyll, 474, 524; Geo. J. Romanes, F.R.S., 474, 548
Nautical Almanac, the, 89
Naval Architects, Institute of, 535, 563
Navigation, a Treatise on, Dr. Merrifield, 169, 237
Nebuchadnezzar, New Inscription of, E. Budge, 375
Nehring (Prof.), Cannibalism among Cave-Dwellers, 366
Nepenthes, Prof. Alex. Dickson, 254
Neva, M. Solokoff's Researches on Water of, 345
Neva Water, Bacterioscopic Measurements of, Dr. Pehl, 557
New Guinea, Mr. Wilfrid Powell's Expedition to, 318
New York, Sunshine Registered at, 111
New Zealand Botanic Garden Board, Report of, 200; Ravages of Coccidæ in, 200; Hop Culture in, 201; the Alps of, W. S. Green, Prof. Bonney, F.R.S., 281
Nice Universal Exhibition, 44
Niger Expedition (Contemplated) by Dr. E. Riebeck, 161
Nilsson (Prof. Sven), Death of, 134; Obituary Notice of, Dr. J. G. Jeffreys, F.R.S., 172
Noblemen during last Three Generations, Weight of British, Fras. Galton, F.R.S., 266
Noe's Thermo-Electric Generators, Prof. von Waltenhofen's Experiments with, 227
Nordenskjöld's Greenland Expedition, 10, 39, 79; Theories in connection with, Prof. Börgen on, 14; Nordenskjöld's Theory as to Navigability of Kara Sea, 14; the Scientific Work of the *Vega* Expedition, 455; Catalogue de la Bibliothèque Japonaise de Nordenskjöld, Léon de Rosny, 594
North Pole, Proposed Italian Expedition to the, 462
Norway, Gray and Black Dust on Snow, 135
Norway Herring Fisheries, 344
Norwegian North Atlantic Expedition: Zoology, 25
Notiosaurus Dentatus, Sir Richard Owen, F.R.S., 327
Nottingham Free Library, Catalogue of Scientific Books in, 317
Novaya Zemlya, Grinevetsky's Explorations in, 346
Nuclein in Animal Body, Prof. Kossel, 352
Nuovo Giornale Botanico Italiano, 613

Oban Pennatulida, the, J. T. Cunningham, 46
Observatories: Ben Nevis, 14; a Christmas Visit to, Prof. G. Chrystal, 219; the Meudon, 64; the New Equatorial at the Paris, 36; Proposed Removal of the Paris, 64, 185, 343, 374, 413, 436, 487: Endowment of the Paris, 226; Chicago, 69; International Polar Observatories, Prof. Wild, 201; Ornithological, in Austro-Hungary, 246; the Torrens, 345; Australian, 390; Sentis Meteorological, 413; Pic du Midi, Pyrenees, 431; Montsouris, 437; Cincinnati, 558; Hong Kong, Dr. W. Doberck, 596; Palermo, 606
Oceanic Linguistic Affinities, Semitico, Prof. A. H. Keane, 172
Ojcow Bone Caves, Prof. Dr. F. Römer, 449
Oldham (J. B.), Meteors, 123
Omond (R. T.), the Remarkable Sunsets, 259
O'Neill's African Explorations, 346
Oosh, Earthquake at, 317
Ophidian Genus Simotes, G. A. Boulenger, 149
Optical Phenomena, J. Ll. Bozward, 102; Dr. H. Airy, A. Tarn, Annie Ley, M. Carey-Hobson, 103
O'Reilly (Prof. J. P.), the Remarkable Sunsets, 180, 549; Dust Atmosphere of China, 260
O'Reilly (M. G. K.), the Ringhals, 278
Ores of Leadville, and their Mode of Occurrence, Louis D. Ricketts, 571
Organic Germs, on the Transmission of, through Cosmical Space by Meteoric Stones, J. H. Stewart, 595
Orholm, the "Jættegryder" of, Herr Geelmuyden, 414
Ormerod (Eleanor A.), Guide to Methods of Insect Life, 308
Ornithological Congress at Vienna, 556, 582, 390
Ornithological Observatories in Austro-Hungary, 246
O'Sullivan (C.), Gums of the Arabin Group, 253
Ostrof Mednij, Exploration of, 605
Oswald's Studies of Chemical Affinity, 391
Otago University Museum, Notes from, Prof. T. J. Parker, 46, 189
"Otto" Gas Engine, Addition of Self-starting Apparatus to, 414
Oudh, Field and Garden Crops of the North-Western Provinces and, J. F. Duthie, 547
Orambo Land, Exploration of, 585
Owen (Sir Richard, F.R.S.), Resignation of, 157; Sceparnodon ramsayi, 165; Skull and Dentition of Tritylodon longævus, 165; an Extinct Australian Lizard (Notiosaurus dentatus), 327; Presentation of Address to, 487
Owen (Sara S.), Unconscious Bias in Walking, 336
Oxford Convocation, Vivisection in, 343
Oxford, Physiology in, E. Chapman, M.A., 76
Oxygen, &c., Liquefaction of, Wroblewski and Olszewski, 95
Ozone at Sea, C. L. Wragge, 336

Pacific, Anthropological Results of Dr. Finsch's Journey to the, 462
Palæolithic Implement found in Clerkenwell Road, 15
Palæolithic Man—His Bead Ornaments, Worthington G. Smith, 83
Palæontology, Chinese, Prof. R. K. Douglas, 551
Palermo, Observatory of, 606
Palestine Geological Expedition, Prof. Hull's, 245, 318; Return of Prof. Hull's, 389; H. Chichester Hart, 384
Palinurus, Prof. T. J. Parker, 189
Pamir Expeditions, Russian, 319
Parallaxes of Southern Stars, Gill's, 273
Parcels, Scheme for discovering Clockwork in, W. de Fonvielle, 437
Paris: the Academy of Sciences, 24, 48, 72, 96, 120, 143, 167, 191, 231, 255, 279, 304, 351, 376, 423, 447, 470, 495, 543, 567, 592; Observatory, the New Equatorial at, 36; Proposed Removal of the Observatory, 64, 185, 343, 374, 413, 436, 487; the Endowment of, 226; Edison Incandescent Lights in Hôtel Dieu, 366; Exhibition of Objects collected by *Romanche* Expedition, 366; Anthropological Society of, 414; Lectures at Geographical Society of, 436; Lighting of Opera House by Electricity, 584
Parker (Prof. T. J.), on some Embryos of Callorhynchus antarcticus, 46; Palinurus, 189
Partials, W. C. Jones, 6; C. O. Varley, 57
Patagonia, Gen. Roca's Expedition to, 451
Paul (H. M.), the Remarkable Sunsets, 284
Paulsen (Adam), on the Height of the Aurora Borealis, 337
Payer (Julius), Contradiction of Report of Death of, 135; Pictures Illustrating Franklin Expedition, 317
Payne (Dr.), the History of Medicine (Encyc. Brit.), 51

Pehl (Dr.), Bacterioscopic Measurements of Neva Water, 557
Pennatulida, the Oban, J. T. Cunningham, 46
Pennington (Rooke), Cats at Victoria Station, 596
Penny Science Lectures at Victoria Coffee Hall, 389
Peripatus, on the Development of, Dr. von Kennel, 62; Prof. H. N. Moseley, F.R.S., and A. Sedgwick, 196
Perpignan, Remarkable Sunset at, 295

Perrier's Map of Tunisia, 488
Perrotin, Close Double-Stars, 185
Perth Natural History Society, 225
Perulta (Raphael), Detonations of Java Eruptions heard at Philippine Islands, 44
Petermann's Mittheilungen, 160, 584, 585
Petit (M.), Return of, from the Congo Region, 158
Petrological Notes on some North England Dykes, J. J. H. Teall, 254
Pettersen (Dr. Karl), Sagvandite (a New Rock), 196
Phenomena Exhibited by Dusty Air in the Neighbourhood of Strongly Illuminated Bodies, Profs. Oliver J. Lodge and J. W. Clark, 417
Philippine Islands, Java Eruption Detonations heard in, 44
Phonograph to be used in African Exploration, 460
Photography of Colours, Greenwood Pim, 470
Phylloxera, C. S. Riley, 87; in Victoria, 245; French Commission on, 389
Physical Notes, 489, 558
Physical Papers, Prof. Stokes' Mathematical and, Prof. P. G. Tait, 145
Physical Society, 71, 142, 231, 350, 399, 446, 495, 541
Physiological Society, 472, 568
Physiology in Oxford, E. Chapman, M.A., 76
Pic du Midi, Studies made on Summit of, with a View to the Establishment of a Permanent Astronomical Station, MM. Thollon and Trépied, 7; Meteorological Observatory, 431
Pidgeon (D.), the Remarkable Sunsets, 195
Pim (Greenwood), Photography of Light and Dark Colours, 470
Pitman (Elizabeth M.), the Remarkable Sunsets, 153
Planet of Heterogeneous Density, on the Figure of Equilibrium of a, Prof. G. H. Darwin, F.R.S., 230
Planets, Minor, 273
Plants (Useful), Christy's Notes on, 488
Plateau, Posthumous Memoirs by, 489
Plummer (W. E.), Solar Motion in Space, 246
Pneumonia (Croupous), Micrococcus in, Dr. Friedländer, 144
Pogge (Dr. Paul), Death of, 584
Poisons, Uterine Transmission of, Dr. Falk, 280
Poisons, A. W. Blyth, 451
Polar Observations, International, Prof. Wild, 201
Polar (Austrian) Expedition, Results of, Lieut. Wohlgemuth, 246
Polar Expedition in A.D. 1266, Icelandic, 416
Polar Congress at Sienna, 416
Polarisation, Galvanic, Explained according to Thermodynamic Principles, Prof. von Helmholtz, 192
Polarisation of Light, Dr. Lecher's Experiments on, 559
Polarity and Neutrality, Magnetic, Prof. D. E. Hughes, F.R.S., 468
Polish Bone Caves, Prof. Dr. F. Römer, 449
Pons' Comet, 45, 104, 112, 185, 273, 296, 367; T. W. Backhouse, 7, 104: Drawings of, 460
Porpitidæ and Velellidæ, the, Prof. Alex. Agassiz, 262
Porto Rico, Baron Eggers on, 129
Portraiture, Composite, Adapted to the Reduction of Meteorological and other Similar Observations, G. M. Whipple, 420
Portuguese Expedition to West Africa, 64, 245
Poulton (E. B.), Heredity in Cats, 20
Powell's (Mr. Wilfrid) Expedition to New Guinea, 318
Poynting (Prof. J. H.), Seismology, 489
Prague, Human Skull Discovered near, 557
Prairies of the Canadian North-West, on the Absence of Earthworms from the, Timothy E. Wilcox, 406
Prehistoric Remains of Britain, the Minor, Local Science Societies and, 19
Prehistoric Burial Ground near Buhla, 460
Pringsheim's Jahrbücher für wissenschaftliche Botanik, 349
Prjevalsky's (Col.) Thibet Expedition, 416; Travels in Central Asia, 593
Proceedings of Isis Natural History Society, Dresden, 23
Proceedings of Linnean Society of New South Wales, 47
Projectiles, on the Motion of, E. Ristori, 572
Protopterus, Mygale, and Scorpions, Prof. E. Ray Lankester, 54
Protozoa, Dr. H. G. Brown on, 5
Prussia, Geological Survey of, 270
Pulborough, Canoe unearthed at, 15
Pumice, Sea covered with, Capt. Barlow, 488

Quadrantids, the, Thos. W. Backhouse, 104
Quaritch's General Catalogue, 212
Quarterly Journal of Microscopical Science, 141

Rabenhorst (Dr.), on Algæ, Mary P. Merrifield, 340
Radiolaria, the, Prof. E. Haeckel, 274, 296
Radford (W.), Waking Impressions, 77
Rae (Dr. John, F.R.S.), Recent Low Temperatures in America, 287; Unconscious Bias in Walking, 311; Wind Sand Ripples, 357; Common Domestic Duck diving for Food, 428; Right-sidedness, 477; Thread-Twisting, 550
Railroad Time, Standard, C. A. Schott, 70
Railway, Cats on the District, E. de M. Malan, 573
Rain and Dew, Salt, H. N. Draper, 77; F. Gillman, 172
Rain-band Spectroscopy Attacked Again, Prof. C. Piazzi Smyth, 525
Rainbow, Circular, J. A. Fleming, 310: J. M. White, 357 T. R. Maynard, 357; Dr. W. H. White, 428; G. K. Gilbert, 451
Rainbow, a Lunar, J. C. Kernahan, 105; C. H. Romanes, 172; M. F. Dunlop, 172; J. A. Fleming, 310; A. P. Colman, 550

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

THURSDAY, NOVEMBER 1, 1883

OOLOGICAL REPORTS OF THE VOYAGE OF H.M.S. "CHALLENGER"

eport on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873-76, *under the Command of Capt. George S. Nares and Capt. F. T. Thomson.* Prepared under the Superintendence of the late Sir C. Wyville Thomson, Director of the Civilian Scientific Staff on board, and now of John Murray, one of the Naturalists of the Expedition. Zoology—Vol. V., 1882; Vol. VI., 1882; Vol. VII., 1883. (Published by Order of Her Majesty's Government.)

THE editor has made most excellent progress in the work of publishing the Reports of the scientific sults of the voyage of H.M.S. *Challenger* during the st year, as the three bulky quarto volumes now before well indicate. Vol. V. contains an elaborate Report on Ophiuroidea by Theodore Lyman, who has made this oup so long his special study, and who has in this onograph given us a most elaborate and beautifully lustrated contribution to science. The memoir contains e description of some twenty-one genera and of 170 pecies, but as several already described species were also ollected, Mr. Lyman has judiciously given not only all ese but also the names of all others previously described, rranged under their genera, constituting therefore this Report a more or less complete monograph of the Ophiuroidea. There are very elaborate tables of distribution, eographical, bathymetrical, and thermal, with brief remarks on their indications, and at the end of these is a note on the fossil forms and their relations to those living. In the descriptive part of the monograph Mr. Lyman has ventured to use simple words as often as possible, so as not to add to "the jargon in which zoology is now smothering."

Amid the three hundred pages of description of species there is of necessity little that will bear transcribing in a general notice of this important work; and still among them we find the following, which in the writer's mind awakened similar emotions to those referred to by Mr. Lyman:—"In my notebook of 1861 I find, '*Euryale exiguum*, Lamk., original of Peron and Leseur, 1803, young.' This prosaic line is poetical to me. It takes me back to the Jardin des Plantes as it was twenty years ago, and I can see the laboratories of the 'mollusques et zoophytes' where I studied under the kindly direction of old Valenciennes. He has gone, and so has his successor Deshayes, and their place is now worthily held by Perrier, who was a very young man when first I knew him. But still that poor little broken *Astrophyton exiguum* lies on its shelf, the survivor. It was with a real emotion that in unpacking the *Challenger* collection I drew from a large jar two fine specimens. I felt like a scholar who had found a duplicate of the Codex argenteus. After more than two generations the unique treasure of the Jardin des Plantes has at last other representatives, and to celebrate its rediscovery I could do no less than give a figure of the animal" (Plate 47).

So far as the geographical distribution of the group is concerned, it would appear that although deep-sea species are more inclined to extensive wanderings than those frequenting shallows, yet, speaking generally, they offer similar differences. Among littoral forms there are those which are found all over the great ocean from the Sandwich Islands to the east coast of Africa, and even south to the Cape of Good Hope. One species, *Amphiura squamata*, is found in the North and South Atlantic, at the Cape of Good Hope, and in Australia. Others, again, are considerably restricted; for example, the abundant fauna of the Carribean Sea, which reaches only Brazil on the south and the Carolinas on the north. *Ophiacantha vivipara* and *Gorgonocephalus pourtalesii* going to 14c and 600 fathoms, are remarkable for their extension in longitude, being found from the Kerguelen Islands on the west to the east coast of South America. As to the very deep-water species, *Ophiomusium lymani* occurs well up in the North Atlantic, in the extreme South Atlantic, near New Zealand, off Japan, and off the south-west coast of South America. *Ophiacantha cosmica* is found off the Brazil coast, between the Cape of Good Hope and the Kerguelen Islands, off the south-west coast of South America, and at intermediate points. Some of these deep-sea species are, however, quite restricted in their

VOL. XXIX.—No. 731

area, such as *Pectinura heros, Ophiomusium validum,* and *Astroschema arenosum,* the first living near the Celebes, the last two in the Carribean Sea. While species differ thus much in the extent of their migrations, there are certain bottoms where they seem to decline to live at all. Thus in all the deep water from the centre of the North Pacific to near the southwest coast of South America, there was not a single Ophiuran found. As to their distribution in depth, a very large proportion live exclusively on the littoral zone, and therein are included species both of cold and of hot water, though the number of the latter is much the larger. Some fifty species live exclusively below 1000 fathoms, and have to endure a degree of cold near to freezing, an enormous water pressure, and an entire absence of sunlight.

The forty-eight, rather crowded, plates have been drawn with skill and fidelity by Miss K. Pierson and Mr. L. Trouvelot with the exception of Plate 48, which represents half of an arm of *Gorgonocephalus verrucosus*, carried out to its extreme twigs, and which stands as quite a monument of patience on the part of Mr. Lyman's assistant, Miss Clark.

The Second Report in this volume is by Prof. D. J. Cunningham, on some points in the anatomy of *Thylacinus cynocephalus, Phalangista maculata,* and *Phascogale calura,* with an account of the comparative anatomy of the intrinsic muscles and the nerves of the mammalian pes. This Report gives details of the anatomy of three little known mammals, representing types which differ widely from each other both in physique and habits. A special interest attaches to the anatomy of the Thylacine, as it is rapidly becoming extirpated. In examining the intrinsic muscles of the marsupial manus and pes, Prof. Cunningham encountered a somewhat puzzling multiplication of the elements. To clear this up and at the same time to connect the condition with that found in other animals he was induced to extend his inquiries upon this point into mammals in general, and we are therefore favoured with the results of this comparative research in a very elaborate report on the comparative anatomy of the mammalian foot.

Vol. VI. contains also two memoirs: the first is a Report on the Actiniaria, by Prof. Richard Hertwig. As a considerable number of specimens did not reach Königsberg until this Report was finished, we are promised a supplementary report to describe these additional forms. Fourteen plates accompany this Report. Beginning with a detailed description of a typical Actinian, we have also a comparative survey of the chief characteristics of the several divisions and genera. Six tribes of Actiniana are distinguished: (1) Hexactiniæ; (2) Paractiniæ; (3) Monauleæ; (4) Edwardsiæ; (5) Zoantheæ; (6) Ceriantheæ. Objecting to Verrill's assertion that all specimens of Actiniæ which are only known from preserved specimens should be thrown away as of no scientific value, Prof. Hertwig has laboured manfully over the unfortunately rather badly preserved specimens of the *Challenger* voyage; and by keeping in view such factors in their description as the structure of the tentacles, of the septa, of the oral disk, of the circular muscle, &c., he has presented a most minute and elaborate description of an immense variety of new forms, the scientific value of which will go without dispute. As the collections of the *Challenger* were for the most part made in the open oceans, the littoral zone, which would have furnished the larger proportion of Actiniæ was almost entirely neglected, and but one littoral species occurs in the list. As a rule the number of the Actiniæ decreases as the depth increases; they have not been observed at a depth of over 2900 fathoms, but the greater the depth the more the fauna was found to vary from that of the coast. Of the twenty-one forms from 500 to 3000 fathoms described, no less than six species are found to have undergone some extreme modifications of their tentacles, whilst a like phenomenon has never been observed in a single one of the forms of the coast fauna, which greatly exceed the deep-sea fauna in number. These alterations lie for the most part in the direction of transforming the tentacles into tubes and openings, and Prof. Hertwig connects this with the nutriment of these deep-sea forms, which is not of a nature to be captured by tentacles.

The Second Report is on the Tunicata, by Prof. Herdman. It is Part I., on the Simple Forms. The collection generally was found to be in a state of excellent preservation, and consisted of eighty-two species, which are referred to twenty genera. Of these, seventy-four of the species and nine of the genera are new to science, but it has not been found necessary to form any new families. The new genera are mostly instituted for very deep-sea species. In several instances the new genera have been of great interest, as they have demonstrated affinities between known forms, and have exhibited combinations of characters which in some instances necessitated a revision of the definitions of old genera, and even affected one's ideas with regard to the characters of the families. The new species are all beautifully illustrated in thirty-seven plates. The memoir has prefixed to it a history and bibliography of the group and a neat and well-written account of its anatomy, which is accompanied by an excellent series of woodcuts. So little is known as to the geographical distribution of the group that Prof. Herdman thinks any generalisation on this head would be of little value. A few facts of interest are, however, mentioned: thus the Tunicata are greatly more numerous in the southern than in the northern hemisphere, and they reach a maximum of abundance in the far south. As to their distribution in depth, the four families are found to have the following limits:—

The Molgulidæ	range from	the shore to	600	fathoms.
The Cynthiidæ	,,	,,	2600	,,
The Ascidiidæ	,,	,,	2600	,,
The Clavelinidæ	,,	,,	129	,,

Seven species were found at depths of from 2000 to 3000 fathoms.

Calcareous spicules are noticed as present in the tests of several species of the genera Culeolus and Cynthia. They are very different in the two genera, being irregularly branched and with smooth surfaces in Culeolus, while they are rod-shaped or fusiform, with their surfaces minutely echinulated in Cynthia. Neither of the two previously known genera in which the test is remarkably modified—Rhodosoma and Chelyosoma—were collected during the *Challenger* Expedition, but two of the new forms show notable peculiarities in the test, Pachychlœna having it greatly thickened all over, while *Hypobythius calycodes*, oseley, has a series of symmetrically placed nodular rtilaginous thickenings in the otherwise thin and mem- anous test. This Report of Prof. Herdman's may be garded as almost a monograph of the Tunicates, and is a st valuable addition to our knowledge of this little own group of forms.

Volume VII. contains four Reports. The first of these by Prof. Morrison Watson, on the anatomy of the pheniscidæ collected during the voyage. The collec- on contained three or four adult specimens of each of he species obtained, preserved for the most part in brine, ut in some instances in spirit, as well as a number of nmature birds taken from the nest, together with eggs various stages of hatching, preserved partly in spirits d partly in bichromate of potash. In the present eport only the anatomy of the adult birds is treated of; at of the young being reserved for a second part. electing *Eudyptes chrysocome* from Tristan d'Acunha as standard, the anatomy of the other seven species is mpared with it; thus in every section the anatomy of standard species is given in detail, and then the riations met with in each of the others is appended. those cases in which no variations are reported the natomy of the forms was identical. The descriptive natomy of the various systems of tissues seems to leave tle to future investigators to record. In the section evoted to osteology, while treating of the bones of the nterior extremity, the author remarks that in several articulars the penguin's wing differs from that of other irds—movements of pure flexion and extension in the ints beyond the shoulder can scarcely be said to be ssible; the articulations, however, admit of a very nsiderable amount of rotation, and consequently, in- ead of the limb being converted into an absolutely rigid addle or oar, the rotation in question converts the wing to a screw-like blade, the curvatures of which are con- ntly varying in accordance with the amount of rotation ich the forms of the different joints permit. Upon care- lly watching a living specimen of Aptenodytes in the ological Society's Gardens, the author observed that e wing of the penguin is never used in the manner of a gid oar, which would imply the simultaneous movement f both wings in the same direction in order to propel the ird. On the contrary, the wings were often and indeed sually brought into use alternately, much in the same anner as the pectoral fins of a fish, and in every move- ent of the wing wiry, screw-like curvatures, which are due the rotation of the different segments of the limbs upon ne another, are strongly developed. In fact, a constant rewing and unscrewing of the separate alar segments pon one another takes place simultaneously with the rward and backward movement of the organ as a hole.

From general considerations of the anatomy of the enguin, Prof. Watson concludes that these birds together rm a natural group, every member of which is possessed f certain anatomical peculiarities which serve at once to ssociate it with its fellows and to separate it from the embers of other groups which may more or less closely semble the Spheniscidæ. From an anatomical point view he would recognise but three genera—Apteno- es, Spheniscus, and Eudyptes. The remarks on the aracteristics of these genera and the limits of the species contained in them are among the most interesting in this Report.

As to the phylogeny of the penguins the author concludes that they form the surviving members of a group which had early diverged from the primitive avian stem, but that at the time when the separation took place, the members of that stem had so far diverged from the primitive ornithoscelidan form as to be possessed of anterior extremities, which, instead of forming organs of terrestrial, had become transformed into organs adapted to aërial progression, or true wings. If this view be correct, palæontological research may, in the course of time, disclose the existence of Spheniscidine remains which may enable us to trace the line of descent of the penguins of the present day from the original avian stem, and through it the relationship which exists between the modern Spheniscus or Eudyptes, with their separate metatarsal bones and aborted wings on the one hand, and the majority of modern birds, with their conjoined metatarsal bones and perfect wings on the other.

The geographical distribution of these birds is of great interest. They are entirely confined to the southern hemisphere, none of them straying north of the equator. Within this area their distribution is very extensive, reaching from the Galapagos Islands on the equator, southwards to the Antarctic Islands. Prof. Watson surmises that this distribution does not depend on temperature, but may depend on a relative abundance of the food supply (Cephalopods and Crustacea) found in the two hemispheres respectively; but the editor, Mr. J. Murray, in a footnote, says: "The penguins reach the equator only on the coasts of Chili and Peru. Now the Peruvian current from the Antarctic skirts along this coast, and takes a low temperature as far north as the Galapagos Isles; the temperature of the sea being there (equator) 62° to 66°, while in the middle of the Pacific (equator) the surface temperature is 81° to 88°. Temperature, therefore, most probably has something to do with the limitation of the geographical distribution of the Spheniscidæ."

The second memoir is by Dr. F. Buchanan White, on the Pelagic Hemiptera collected during the voyage. These, the only truly pelagic insects, belong to the genera Halobates and Halobatodes. The first of these was founded sixty years ago by Eschscholtz for three species taken during the well-known voyage of Kotzebue round the world. But few species are known, and they are very rarely to be found in collections, though they seem to be abundantly distributed in tropical seas. Their structure would seem to indicate that they are archaic forms of great antiquity, and as doubtless many species yet remain to be discovered, it is to be hoped that some one with the will and the opportunity will be found to turn their attention to the group. In the meanwhile Dr. White has in this Report given a detailed account of the literature of these genera, followed by an account of the anatomy and description of the genera and species. Of the genus Halobates he describes eleven species, of which three were first described by Eschscholtz, one each by Templeton and Frauenfeld, and six for the first time in this memoir. In his remarks on the species we notice that, after a very bad fashion adopted by some entomologists, these are alluded to under their trivial names only, thus; "according to Frauenfeld, *micans* differs from *willerstorfii*." This is the only departure from the ordinary rules of nomenclature that we have as yet noticed in these Reports, and we call attention to it in the earnest hope that it will not occur again.

Species of Halobates are recorded in Mr. Murray's journal as found twenty-one times in the Atlantic between latitudes 35° N. and 20° S., and thirty-eight times in the Pacific between latitudes 37° N. and 23° S. The majority of the specimens taken by the tow net were dead when brought on board, but some were taken alive and were observed skimming over the surface of the water in the glass globes. On one occasion a species was seen to dive. Of the species of Halobates now known, five occur in the Atlantic, but one only is restricted to that ocean, though the headquarters of another appear to be there. Six species, of which two are peculiar, occur in the Indian Ocean west of long. 100° E., while to the east of this, and chiefly in the West Pacific, eight species occur, of which four are restricted to that region. But taking the West Pacific and Indian Ocean together, we find that nine out of the eleven known species occur there, and five nowhere else. Of Halobatodes *H. lituralus* occurs in the Chinese Sea, *H. compar* is from India, *H. stali* from Ceylon. All the species are figured on three plates.

The Third Report is by Prof. Allman, on the Hydrozoa. Part I. Plumularidæ. Of the Hydroids, a large number of exotic species have been recently described, notably the collections made during the exploration of the Gulf Stream, and during the expedition of H.M.S. *Porcupine*, by Dr. Allman himself. But to this number the collection brought home by the *Challenger* makes a large and valuable addition. Of this collection the family of the Plumularidæ forms a considerable proportion. Only one form can be identified with a species occurring in the European seas. This species, *Cladocarpus formosus*, was dredged by the *Porcupine* from the seas lying to the north of Scotland, and by the *Challenger* from the seas at Japan. It is a well-marked species, and the great distance between the Atlantic and Pacific stations, without any intermediate station having been discovered, is a remarkable and significant fact. By far the larger number of the forms brought home by the *Challenger* consist of species new to science, while among these a considerable number have had to be assigned to new genera. Many of the species are of great interest from the light they throw on the external morphology of the group, and from the aid which they afford towards a philosophical conception of the significance of parts otherwise enigmatical. The Report is prefaced by some introductory remarks on the general morphology of the Plumularidæ. While not yet possessing the data necessary for a complete exposition of the geographical distribution of this group, it may be generally asserted that it attains its greatest development in the warmer seas of both hemispheres, and that in tropical and subtropical regions it has its maximum in multiplicity of form, in the size of the colonies and in individual profusion. The dredgings of the *Challenger* and of the United States Exploration of the Gulf Stream would further seem to point to two centres of maximum development within the area thus indicated—an eastern centre, which is situated in the warm seas around the Philippines and other islands of the East Indian Archipelago, and a western centre, which will be found in those which lie around the West Indian Islands and bathe the eastern shores of Central and Equinoctial America. In bathymetrical distribution the Plumularidæ present considerable variation. Among the species described some are quite littoral, having been dredged from depths ranging from between 8 and 20 fathoms. The greater number, however, have been obtained from depths between 20 and 150 fathoms, while three species, *Aglaophenia filicula*, *A. acacia*, and *Polyplumaria pumila*, are from a depth of 450 fathoms. The striking and beautiful genus Cladocarpus consists of eminently deep-water forms, and of the two species described, one—*C. formosus*—was obtained in the Japan seas from a depth varying between 420 and 775 fathoms; the same species from the north of Scotland was found at depths of from 167 to 632 fathoms. The second species—*C. pectiniferus*—was dredged off the Azores from 900 fathoms, being the greatest depth from which any Plumularidan is known to have been obtained. This Report is illustrated by twenty plates.

The last Report in this volume is on the genus Orbitolites, by Dr. W. B. Carpenter, with eight beautiful plates by Mr. George West, jun. Some thirty-six years ago Dr. W. B. Carpenter received from Prof. Edward Forbes some small discoidal bodies which had been dredged between 1842 and 1846 by Prof. J. Beete Jukes on the coast of Australia, with the hint that these were probably the Marginopora of Quoy and Gaimard. From this time to the present Dr. Carpenter has made a pretty constant study of these interesting Foraminifers, and he gives us a highly instructive account of the views held from 1823 by the various authors who have written on the genus, from the strange misconceptions of Ehrenberg to the accurate descriptions of Prof. Williamson, who first clearly determined the close affinity between Orbitolites and Orbiculina, thus disposing of the Bryozoic doctrine of Ehrenberg, and relegating these organisms to the Foraminifera. As the final result of Dr. Carpenter's laborious researches on this group, he concludes that while the ordinary notions of species will not apply to it any more than it will to any of the Foraminifera, still particular types of form are transmitted with marked genetic continuity, and he distinguishes four very well marked types of Orbitolites, around which the entire assemblage of specimens collected over a very wide geographical area, and from a great bathymetrical range, can be grouped without difficulty. Treating of the subject of descent, the author declares that "it seems to him that the evolution of this type from the simplest monothalamous Milioline has taken place according to a definite plan, of which we have the evidence in the wonderful uniformity and regularity of the entire sequence of developmental changes, whilst we are entirely unable to account for those changes without attributing to the subjects of them a capability of being affected by external agencies or modes so peculiar as to indicate a previous adaptation."

From an editorial note prefixed to this volume we learn that the various large incidental collections of terrestrial forms, such as insects, spiders, reptiles, &c., will not have any detailed reports published concerning them, but that they will be referred to in the narrative of the cruise, the first volume of which is announced for 1884.

OUR BOOK SHELF

Elementi di Fisica. Vol. IV., Elettricità e Magnetismo. By Prof. Antonio Ròiti. (Florence, 1883.)

URELY, and not slowly, the views of Thomson, Maxwell, d the modern electricians generally are finding accept- ce throughout the Continent. The absolutely unani- ous acceptance of the British Association's system of lectrical units since the indorsement of that system by he Paris Congress of 1881 has proved the immense gain o the electrical world of having a uniform means of ex- ressing electrical quantities, and has compelled elec- ricians not only to read but to comprehend the writings f the pioneers of this most important reform. The work ow before us for review, though professing to be but a xt-book for use in the lyceums and schools of Italy, ves ample evidence that its author, Prof. Ròiti, of the oyal Institute of Higher Studies in Florence, is not nly abreast of all the latest developments of electricity, ut that he has mastered the theory also. Few text-books f its size have we seen that will compare favourably with rof. Ròiti's little volume of 356 duodecimo pages. The ults which have been hitherto so conspicuous in most the Continental text-books on electricity are in this ork conspicuously absent. As an example we may efer to the author's treatment of the relation between the apacities, potentials, and charges of similar conductors. The elementary theory of the magnetic shell and that of the mutual potential of two magnetic shells are eatly expounded in pages 131 to 133. The absolute lectrometer and the quadrant electrometer of Sir W. Thomson are both described, and illustrative figures given. The system of absolute and derived (C.G.S.) units, and that of the practical units of electric quantities based upon them, are explained at length on pages 204-5. There is a short chapter on the electric light, and another on electric motors, in which the *anello elettro-magnetico di Pacinotti* is described, the author remark- ng with emphasis that it contained the germ of almost ll the machines by which the marvellous strides recently made in the applications of electricity have been achieved. The experiments of Deprez at Paris on the electric ransmission of power, and the economic questions volved are also touched upon. Crookes's researches n "radiant matter" are mentioned and illustrated. Amongst points of novelty may be mentioned Pellat's method of measuring the electromotive force due to polarisation, which has not yet, we believe, found its way into any English text-book. Two points of criticism we have to offer in conclusion. The first is that the author defines electric *tension* as identical with the electric *force*, equal to 4π times the surface density of the charge, instead of defining it, in the sense of Faraday and Maxwell, as the stress on the dielectric, which is proportional to the square of the surface density, and therefore proportional also to the square of the electric force or electromotive intensity at the point of the surface considered. The only other complaint we have to make of the work—and this does not detract greatly from its value—is that the author does not acknowledge the sources from which some of his descriptions and cuts are taken. S. P. T.

Dr. H. G. Bronn's Klassen und Ordnungen des Thier-Reichs, wissenschaftlich dargestellt in Wort und Bild. Erster Band, Protozoa. Neu bearbeitet von Dr. O. Bütschli. (Leipzig and Heidelberg: C. F. Winter, 1880-83.)

THE first nineteen parts of this new edition of vol i. of Dr. Bronn's well known and important work on the classes and orders of animals, nearly completing the volume, prove that Prof. Bütschli has spared no pains to keep up to the most modern investigations of the Protozoa. n no one division of the animal kingdom has observation one so hand in hand with discovery as in this, the lowest of her classes. Glancing at the portion treating of the Gregarinida, what strides have been made in our knowledge of these forms within the last ten years. Adopting Leuckart's titles for the class of Sporozoa, under which are the sub-classes Gregarinida, Coccidia, Myxosporidia, and Sarcosporidia, we find 137 pages and eight plates crowded with figures devoted to a sketch of the characteristics of the class with diagnoses of the genera and the number of species, and references to the places where fuller details of these latter will be found. The illustrations are clear and effective, and copied from every available source. The bibliography appears to be well to date, and this volume when complete will be an indispensable handbook for the student of the lower forms of animal life.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

"Elevation and Subsidence"

THE view that the glacial subsidence was due to the pressure of the accumulating land ice, has been accompanied with the corollary that subsequent elevation was due to the removal of this pressure by the melting of the ice; but though I think the first is true, the corollary is not so, in England at least.

In my memoir "On the Newer Pliocene Period in England" (*Quart. Journ. Geol. Soc.* for 1880, p. 457, and 1882, p. 667), I have endeavoured to show how the inclination of this country changed during the progress of the major glaciation, and the flow of the land ice from the mountain districts to the sea altered in accordance therewith, as well as pointed out (p. 709) the connection of this change of inclination with the accumulation of the land ice on the mountain districts; but I have also traced in detail in it how the east side of England rose to an extent that brought Norfolk and Suffolk from a submergence of more than 300 feet to their present level at least, and Essex proportionately so, while the land ice continued to push over the sea-bed of sand and gravel, as this rose into land, covering it with its moraine, until by this rise the easterly movement of the ice was arrested, while the west and south of England still remained to a great extent submerged. Since that memoir was published, Mr. David has in the same journal described the glacial clay which represents the moraine of the Welsh land ice in East Glamorganshire, itself *un*covered by any marine deposit, as covering beds of stratified sand and gravel, which, from their containing many chalk flints, can be only the bottom of the antecedent sea, as low down as 80 feet above Ordnance datum. When this is compared with the evidence of more than 1300 feet of submergence afforded by the shell bearing gravels of North Wales; of 700 feet afforded by the Gloucestershire gravels to the east; and of between 500 and 600 feet afforded by the gravels of Devon to the south of Glamorganshire, it becomes evident that the amount of rise which took place in the west of England before the land ice began to retreat was even greater than in East Anglia. It is to subterranean movements engendered by this pressure, and not to its removal, that the rise in England seems to me to have been due; and I have given several sections in this memoir in illustration of the abrupt and violent character of the upthrows connected with it.

Although in this memoir I remarked upon the coincidence of the westerly increment in the great submergence with the augmenting quantity of the land ice on Cumberland, Westmoreland, and Wales, as the major glaciation went on, yet this coincidence between augmenting land ice and submergence is, I now see, more complete than had then occurred to me; for though I described the evidences that show the passage from the Crag to the glacial marine beds of Norfolk and Suffolk to have been accompanied by a northerly subsidence which submerged the valley of the Crag river, in the north of the former county, while the other extremity of its estuary (in East Suffolk) was elevated, so that islands formed of Crag beds came there into existence, around and up to which the earliest glacial marine accumulations of sand and shingle were bedded, and which, as subsequent southerly and westerly subsidence ingulphed all but the highest downs of the south of England, eventually spread over these islands, yet I did not connect this first movement with the pressure of the land ice. I have since, however, perceived that this connection exists; for, as the Glacial period came on, the precipitation must necessarily, on account of latitude, have taken more exclusively the form of snow in Scotland before it did so in Cumberland and Wales; and, by thus accumulating land ice earlier in Scotland, caused this northerly subsidence. As the cold increased the precipitation in the form of snow reached its maximum in Westmoreland and Cumberland, and yet later somewhat in Wales; and as it did so, the pressure of the land ice engendered by it turned the depression increasingly in those directions, so that eventually all England, save the highest downs, and even the lower ends of the river valleys of North-Western France became submerged proportionately to their contiguity to the foci of pressure. These increments of depression I have in this memoir traced by more than one train of evidence, and shown how this change of inclination, by diverting the directions taken by the land ice to the sea, changed also the character of the materials of which the resulting morainic clay is made up, and so gave rise to those Upper and Lower clays of the major glaciation in Yorkshire, which have been seized upon to support the hypothesis of alternations of climate during that glaciation.

The connection between the augmenting weight of the land ice and subsidence seems to me so clear, that I cannot but think that American geologists have fallen into an error, in regarding the Champlain period as belonging to the wane of the great glaciation, instead of to its culmination. It seems to me that although the increasing volume of the land ice in the Lake (or St. Lawrence) basin caused this ice at its western extremity, where the parting between the two basins is very low, to invade the upper part of the great Mississippi basin, yet its weight where thickest—that is to say, towards its eastern extremity, which was that of greatest snow precipitation—so pressed this extremity down that the seaward termination of this ice in the Gulf of St. Lawrence retreated before the greater depth of sea there which thus resulted, and so allowed the sea to penetrate to Montreal and Lake Champlain, near the former of which places the remains of its inhabitants have been left at an elevation of about 600 feet.

With all this, however, we must not be led into regarding all movements of subsidence as a result of increasing accumulations, whether of sediment or otherwise; for such is evidently not the case, though to instance this would lead me beyond the object of this letter. SEARLES V. WOOD

Martlesham, near Woodbridge, October 11

THE above remarks require but little comment, and chiefly tend to show that Mr. S. V. Wood attaches increased importance to the idea that weight produces subsidence. He speaks of elevation commencing before the retreat of the glaciers, but that they would be enormously lightened before retreating is a fact that I can hardly suppose he has overlooked. In ascending the Jungfrau many years ago, when the Swiss glaciers were diminishing, I crossed from the Grindelwald on to the Aletsch, and had to descend a cliff of nearly vertical ice, which my recollection tells me was some sixty feet high, in order to pass from one to the other. The difference in level was caused by the extra rapid melting of the Aletsch, owing to its more southern aspect and exposure to the Föhn wind. This was at the head of the glacier, and the melting was much more rapid lower down, though the superficial area had not contracted to any appreciable extent. This loss of weight would lead to elevation long before the disappearance of the ice. J. STARKIE GARDNER

Snake Bite

I WAS an eye-witness to the following:—My brother was walking within a field of the Land's End when he stooped to pick up a large snake, apparently nearly a yard long, which bit him on the thumb. The bite became very painful in a few moments, and we realised for the first time that it was poisoned. In less than five minutes he was in the hotel and swallowed half a pint of neat brandy, and soon after some ammonia and water, without any effect. The wound had been well sucked and was steeped in ammonia, but the arm soon swelled to the size of the body, and the swelling began to extend down the ribs. The thumb was lanced while immersed in hot water, and the result was similar to the first gashes in a shoulder of mutton, the exposed flesh being dark mulberry colour, and not a drop of blood flowing. He recovered in seven or eight days, but was weak for some time. J. S. GARDNER

Park House, St. John's Wood Park, N.W.

The Observation of Meteors

ACCOUNTS of large meteors form a frequent subject of correspondence in the columns of scientific journals, but it is not often the case that the descriptions of these phenomena are sufficiently exact to be valuable for purposes of calculation. Rough estimates of the direction and position of flight are of little utility, and the vague statements often made occasion an endless source of difficulty in the satisfactory reduction of results. It is true that observers of fireballs are generally taken unawares by the suddenness of the apparitions, and that the visible paths are seldom to be noted accurately. Before the observer collects himself to record the facts of the display it has disappeared, and he has to rely solely upon the impressions retained in his memory.

But, notwithstanding this drawback, the observations of large meteors as published from time to time would possess far greater scientific value if observers would attend more scrupulously to that most essential detail, the *direction of flight*, and express it by some method of uniformity. Sometimes we find the path vaguely stated as being from "east to south," without any attempt to estimate the altitude of the beginning and end points of the course. On other occasions a meteor is described as passing above or below certain stars or planets. The latter method, though an improvement upon the former, is to some extent indefinite, and therefore unsatisfactory, as giving unnecessary trouble to those who undertake the reduction of such materials. For instance, a meteor is observed early in August, 1881, shooting from "some distance below Saturn towards Comet B." Now in reducing this account troublesome references have to be made to find the places of the two objects on the dates mentioned, and then we are left to guess at the "distance below Saturn" implied in the description. These objections would disappear, and the comparison of observations be greatly facilitated, could observers be induced to give the right ascension and declination of the beginning and end points of the visible paths. These elements admit of ready determination by projecting the observed flights upon a star chart or celestial globe and reading them off. Even in cases where the observations are uncertain, the observer should fix the path according to this method as nearly as possible, for it is manifest that it is infinitely preferable to the vague and often worthless attempts to guess altitudes, compass bearings, &c., and, moreover, it renders the after comparison of observations a work of greater facility and precision.

Though the direction of flight is the all-important element to be determined by meteor observers, there are some minor points which should also be carefully recorded. The time of appearance, brightness, approximate duration, and whether accompanied by phosphoric streaks or spark trains, are each important in their way, and must be stated whenever feasible. If this were done more systematically, the observations of fireballs would acquire additional value, and may quite possibly develop some new facts either as to their appearance or origin.

Bristol, October 22 W. F. DENNING

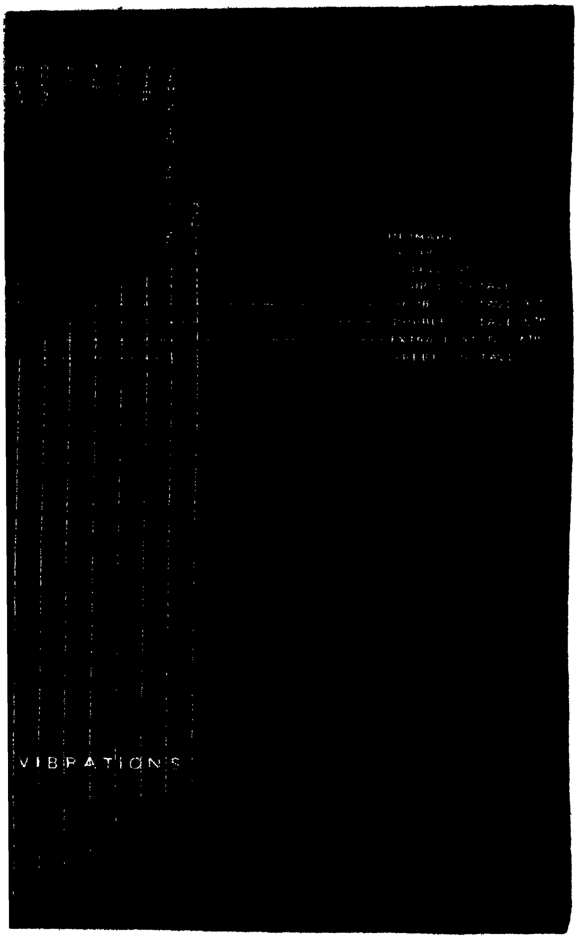
"Partials"

IT is a well known fact that no musical sound is produced alone, but the instant it is sounded a series of other sounds springs from it, and always in a certain order and ratio. Next to the primary tone, the octave is heard, then the octave fifth, the double octave, the double octave third, the double octave fifth, the extra flat double octave seventh, the treble octave, and so on. The origin of these "partials" has long been an interesting study, and a solution has occurred to me which I think is the true one.

We have the fact that an object seen by the eye for ever so short a time leaves its impression on the optic nerves about the eighth of a second *after it has passed away*. By analogy it seems highly probable that all our nerves, including those of the ear, retain impressions made upon them for a momentary period after the cause has ceased to act. If this surmise is correct, then the following would ensue. All musical tones being produced by vibrations striking upon the ear in rapid succession, the first vibration would continue to be felt during the strokes of a number of succeeding vibrations.

The second vibration coming upon the ear before the first ceased to be felt would produce the effect of two in the time of one, making the octave sound.

The third would produce the effect of three in the time of one, making the octave fifth; the fourth, four in one, the double octave; the fifth, five in one, the double octave third, and so on,



he order *exactly corresponding with that in which the partials re heard.*

Of course while the successive strokes occur the first is be-oming fainter in effect, and thus each partial in the above order s heard with fainter intensity.

What the first vibration is to the second and its successors he second vibration is to the third and its successors, and thus he series of partials is kept up as long as the primary tone exists. This also accounts for the strong partials heard in the rough ibrations of the harmonium and the few partials heard from he smooth tones of the flute. W. C. JONES

Chester, October 18

The Green Sun

ON Sunday, September 9, the residents in Colombo, while njoying their evening stroll on Galle Face, were astonished by strange appearance in the heavens. The sky was cloudy, and requent squalls were passing over the sea, one of which just touched Colombo. As soon as it was past, the sun emerged from behind a cloud, of a bright green colour. It was then about 10° above the visible horizon. The whole disk was distinctly seen, and the light was so subdued that one could look steadily at it; indeed I should say its intensity was scarcely half that of the full moon. The same phenomenon was also observed on Monday and Tuesday. Wednesday was overcast, and I have not heard of any observations being made; and on Thursday the sun had resumed its normal appearance. I was not in a position to observe it in the morning; but from reports from other parts of the island I learn that the sun appeared green at its rising, and afterwards changed to blue, like the flame of sulphur, giving little light till it had attained an altitude of about 20°, when it could no longer be watched with the naked eye. During the day the light had a bluish tinge; and in the evening the same phenomena were repeated in inverse order. The moon also, to some extent, was affected in the same way.

Can any of your correspondents give an explanation of this? It has been suggested that a convulsion in the sun may have given prominence to vapours emitting a green light; but to me it seems more probable that the cause is to be sought in the upper strata of the earth's atmosphere. Can it have any connection with the recent volcanic eruption in the Straits of Sunda?

Colombo, September 19 W.

IN a clear sky, as the disk of the sun sinks down beneath the horizontal line of the ocean, the parting ray is a brilliant emerald green. I have occasionally, but not often, had the pleasure of seeing this interesting phenomenon, as the clear atmosphere has to be accompanied with a cloudless region of the sky where the sun is setting. The same effect is not produced by the sun setting behind a distant bank of clouds. Probably the first ray from the rising sun would be the same unexpected colour.

Pons' Comet

THIS comet already has a tail, though a very faint one. With a 4¼-inch refractor I traced it last night to a distance of 20′ from the nucleus, at a position angle of about 75°.

Earthquake

SEEING in your last issue (vol. xxviii. p. 623) that Mr. Cecil describes two distinct tremors of earthquake felt here by him, I write to say that the same phenomena were experienced by myself. I was disturbed in the night by what I mistook for an alarum going off, but found that it was a glass on my water-bottle vibrating violently. After a short pause the glass again vibrated. I found next morning that I could exactly reproduce this sound by shaking the washing-stand. I have never known the washing stand to tremble before, even in a gale.

STUDIES MADE ON THE SUMMIT OF THE PIC DU MIDI WITH A VIEW TO THE ESTABLISHMENT OF A PERMANENT ASTRONOMICAL STATION[1]

THANKS to the indefatigable zeal of General de Nansouty and the engineer Vaussenat, a meteorological observatory has already been erected on the Pic du Midi. After visiting the place with the Director of the Higher Instruction on the occasion when this observatory was handed over to the State, Admiral Mouchez came to the conclusion that it might be possible to establish an unrivalled astronomical station on the summit, which is now perfectly habitable. In the month of August last he did us the honour of requesting us to study on the spot the advantages and possible drawbacks attending an installation made under such exceptional conditions. The details of our observations will form the subject of a special memoir far too extended for insertion in the *Comptes Rendus*. For the present our remarks must be limited to a simple communication of the more interesting results obtained by us from August 17 to September 22.

---

[1] Note by MM. Thollon and Trépied, from *Comptes Rendus* of October 15.

On reaching the summit of the Pic du Midi (2877 metres), where the barometer maintains a mean height of 538 mm., everything presents itself to the observer as if the density of the veil formed above him by the atmosphere were diminished by about a third. The aërial region left behind him being unquestionably the most charged with mist, dust, and aqueous vapour, he may expect to find at once more light and less diffusion. Thus, during the mornings of September 19 and 20, by masking the sun with a screen held at some distance, and exploring the surrounding space with a small spectroscope with an aperture of 0·02m., we were able to observe the planet Venus at a distance of 2° from the solar disk. We could even subsequently distinguish it with the naked eye. But what most surprised us was the marvellous definition at this station. The limb of the sun projected on the slit of a spectroscope showed a spectrum with a boundary as sharp as if produced by a punching machine. We can positively state that we never elsewhere saw anything similar either at Nice, in Italy, Algeria, or even Upper Egypt. We should add that this complete absence of undulation was noticed only in the morning. After the slopes of the mountains had been exposed for several hours to the heat of the sun, the undulations were produced as they are everywhere else, and even became excessive for the rest of the day.

During clear nights, using a telescope with an aperture of 0·16m., and a reflector by Henry of 0·20m., we found the perfect definition observed in the case of the sun in the morning reproduced in the case of the moon, planets, and stars. Under such conditions observations of extreme precision could certainly have been obtained.

For the study of solar physics we had set up the horizontal telescope and the large spectroscope which we usually employ. On observing the solar spectrum at a favourable moment, it seemed streaked in its entire length with a considerable number of fine lines, some bright, others dark, at a mean distance of 3″ of arc from each other. They certainly belonged to the solar image, for they followed all its displacements, and they could have arisen from the granulations of the photosphere alone. Under the same conditions, that is, when the images were perfectly still, the hydrogen bands C and F had no longer any sort of continuity, but seemed formed of distinct bright and dark fragments, of the same magnitudes as the intervals between the lines.[1] This phenomenon was observed not merely at certain times and places, but constantly over the whole surface of the disk. We feel satisfied that the chromosphere presents a system of granulations analogous to that of the photosphere. The two systems thus superimposed become separated in the spectroscope, yielding, one a continuous, the other a linear, spectrum, and blending together in the telescope as on a photographic proof. If this chromosphere, thus rendered visible on the full disk, happened to be traversed by a protuberance, the band C increased in luminosity and for a greater length. By giving sufficient breadth to the aperture, we were then able to observe the protuberance itself, as when on the edge, although naturally with less brilliance, and foreshortened. Nor is this the first instance of protuberances thus observed on the full disk. On this subject the delicate observations of Young and Tacchini are well known. But instead of being accidentally visible, instead of being produced only under special circumstances, as for instance in the neighbourhood of a spot or on the bridge of a spot in process of segmentation, these phenomena were constant for us with varying degrees of intensity, and under the sole condition of using an image entirely free from undulations.

The observations made outside the edge of the solar disk were no less pregnant with results. We know that in the spectrum of the chromosphere there are eight lines always visible under ordinary conditions. On the Pic du Midi, during the five days when we were able to make our records at favourable moments, we saw the number of these bright lines always visible increased to over thirty in the portion of the spectrum which is comprised between D and F. Here we subjoin a table of the wave-lengths of these lines :—

It will be seen that, at the altitude at which our observations were made, an approach was made to the conditions prevailing during a total eclipse.

To resume. The observations we were able to make on the Pic du Midi during the five weeks of our sojourn on its summit justify us in concluding that science will gain much by the completion of the astronomical station begun by the directors of the Paris and Pic Observatories. Here we should have a permanent establishment always open to *savants* wishing to undertake special researches. To mention those points only towards which our attention was mainly directed, we are of opinion that good opportunities would here be found of furthering the solution of many problems connected with solar physics and the spectral analysis of the stars.

THE WHEAT HARVEST OF 1883

THE public must be somewhat puzzled with the divergent opinions of authorities upon the yield of the wheat crop of the present year. On the one side, for example, stands Sir John Lawes with his accurate balances and wonderful wheat field, which experience has taught him usually proves a fair criterion of the yield of the English crop. On the other side is arrayed a somewhat formidable party, which we may take as well represented and led by the very able article in the *Times* of Saturday last, headed "The Result of the Harvest." To put the matter briefly, there is a difference of opinion as to whether we have reaped an average crop or an under-average crop of wheat. And there is also a good deal of difference in opinion as to what an average crop is. The point of greater interest no doubt to us is whether we have just secured an abundant harvest or not. It is a point of very great importance not only intrinsically but as a matter of opinion. If business men believe that our national wealth has been recently increased by an unusual augmentation of our food supply, they may make this opinion a basis for enterprise or speculation. If the opinion which prompted them to action should prove a false one, the results would be inflation, panic, and loss. It is therefore very essential that public opinion should be guided in a right direction upon this important point. Any person who has read our leading newspapers carefully upon the subject of harvests for a series of years will probably have observed a tendency to over-estimate production. The prospect is usually depicted *couleur de rose*, and the public is congratulated upon its harvest prospects, while practical farmers remain in doubt as to the yield of their cornfields. Of one thing we may be certain—that wheat needs heat. The average temperature of our islands is scarcely suitable to the wheat plant, which is rightly viewed as somewhat exotic in its requirements. A slight elevation above the sea-level, or a slight decrease in solar heat, invariably lowers the yield of wheat. Properly read with regard to its distribution throughout the season, the temperature of the summer months ought to guide us to a judgment with regard to the probable yield of wheat. It is the same with regard to wine. Good wheat and good wine years run together. 1868, 1870, and 1874 will probably all continue to be remembered as good wine years, and they are well known as among the best wheat years of the present half-century. In judging as to the effects of temperature upon the wheat crops, we must not only take average temperature but fluctuations between night and day. A single cold night may do incalculable damage, and a few cold days at blooming time may do much to blight a wheat-grower's prospects. Those who watch the weather closely will usually lay the foundation of a sound judgment upon wheat prospects. We require, first, a good seed time; second, a dry March; third, a hot June, July, and August. So much for the weather. We require also a good "plant," *i.e.* plenty of young wheat plants uniformly scattered over the surface. The growing crop must be fairly free from those unaccountable visitations known as "blights," both insect and vegetable, and if we can secure these good conditions we reap a good wheat crop. Let us then endeavour to apply these rules to the actual state of things during the months between seed time of 1882 and harvest of 1883, and let us glance at the various opinions expressed as to the yield of wheat for the present year in the light of these facts. First, then, we passed through a period of incessant rainfall during the time when farmers usually sow their wheat. A worse seed time we have rarely experienced. Constant rain and destructive floods were the characteristics of October, November, January, and February last. Now we owe to Sir John Lawes, in a great measure, the knowledge of the fact that a wet winter washes out that element of fertility which of all is the most important, namely, the nitrates. Here then we have to record a very wet winter, in which seeding was interrupted and nitrates were washed through into the drains and subsoil, and that to an unusual degree.

---

[1] These phenomena referred to by Messrs. Thollon and Trépied were observed and recorded in England under exceptionally fine atmospheric con-

The consequence was that in the spring a thin plant was the rule upon all stiff soils. After this the wheat improved under the influence of a singularly fine spring, and farmers rejoiced in the opportunity afforded them to get on with their root cultivation. Unfortunately this state of things did not last. At the most critical period for the wheat crop summer forsook us. The nights became bitterly cold in June, and a continuation of wet weather set in which lasted almost up to harvest. Accompanying this untoward state of affairs were blights, and the ears became greatly affected with wheat-midge, smut, and ear-cockle, so that wheat-growers became sensible that their main crop was in extreme danger of ruin, and that before the papers began to publish their estimates.

This feeling among wheat-growers was quite general, as they knew that empty ears could not lead to full measures. Examination of the ears just before harvest showed clearly that small and shrivelled grains were only too common, and that many of the florets were barren. Accordingly crops were valued low, and the results from the threshing machine are bearing out the wisdom of these low valuations. As to Sir John Lawes' estimates, based on the experimental field at Rothamsted, no one knows better than Sir John that this coincidence between his average yield and that of the country generally must be liable to be upset by local disturbances. As a criterion of the harvest Sir John Lawes' field may be useful, but certainly cannot be infallible. A local frost, a local hailstorm, a local loss of plant, or faulty cultivation, must be always liable to affect any field and rob it of its general average character when compared with the harvest of millions of other acres. All this is simple truth, and in this season we are inclined to think that Sir John's field "told a flattering tale." The opinion of the writer of the present article is based, first, upon the meteorological conditions to which the wheat crop was exposed during its growth. Secondly, upon his own experience as a grower. Thirdly, upon information obtained from other growers, and from observation and reading.

He has come to the conclusion that the wheat crop of 1883 is below an average, and will be disappointing to the grower. Not only was the crop subjected to many bad conditions during its growth, but a large proportion of it was badly harvested, and is now in wretched condition. If we are not deeply disappointed with the 20 to 26 bushels of wheat per acre which our own liberally treated crops are yielding of *marketable* corn, it is because we have never expected more since those frosty nights of last June, when we resigned our hopes of a good wheat crop. The subject is almost too long for treating in a single article, and we must leave it here. If space had permitted, we should have entered upon the question as to what constitutes an average crop of wheat—a point upon which we appear to be in a state of great ignorance, unless we are to believe that an average which thousands of our best farmers have not been able to touch for the last ten or twelve years is that of the entire country with its millions of badly cultivated acres. This we cannot admit, and after a careful study of the estimates made as to average yield in various counties, we are driven to the same conclusion as that of the writer to the *Times* last Saturday, namely, that little reliance is to be placed upon them. Average, over-average, and under-average are somewhat vague terms, and difficult to fix. We can, however, base an opinion upon the fact that cheerless, cold, and wet summers that are unfavourable for fruit, bees, and vines, or even to pleasure parties, lawn tennis, and picnics, are not going to be favourable to wheat-growers. We have not touched upon barley and oats, but are prepared to allow that circumstances have been more favourable towards these crops than towards the most important cereal. JOHN WRIGHTSON

College of Agriculture, Downton, Salisbury

ON A NEW METHOD OF SINKING SHAFTS IN WATERY, RUNNING GROUND

WHEN an attempt is made to sink a shaft in very watery deposits of gravel, sand, and mud in the ordinary way—that is, by digging out the solid matter by hand and pumping the water to keep the bottom dry—it is found that, after a certain depth has been reached, the current of water which flows up through the bottom brings solid matters along with it as fast as they can be removed, and further downward progress is then completely arrested. Under these circumstances it is necessary to resort to certain special methods of sinking, two of which have been hitherto employed with more or less success. According to one of these methods the shaft-lining consists of an air-tight iron cylinder fitted with an air-tight cover. When the excavation is continued below the natural level of the water, compressed air is forced into the interior of the shaft so as to drive back the water and leave the bottom dry. The workmen can then stand in the bottom and remove the solid matter by hand as easily as if the ground had been naturally free from water. The lining sinks downward as its lower end is laid bare, and is lengthened at the top as required. The pressure of the air is gradually augmented as the depth increases, but unfortunately this process cannot be carried beyond three atmospheres without prejudicially affecting the health of the workmen. When the depth of the watery running ground surpasses the limit represented by a pressure of three atmospheres, it is necessary to resort to the second method. In this case the water is allowed to stand at its natural level in the shaft, and the solid matters are removed from the bottom by a revolving dredger. The lining or casing consists of a cylinder of masonry or iron provided with an iron shoe or cutting ring, and sinks downwards at first in virtue of its own weight, being lengthened at the top as in the previous case, but after a time it generally becomes necessary to force it down by the pressure of screws, assisted by the blows of an instrument resembling a pile-driver. When it cannot be made to sink deeper, another similar cylinder of smaller diameter is introduced into its interior, the same series of operations are again gone through, and so on until the solid ground is reached.

Simple as the last described process may appear, its application is sometimes attended with difficulties of almost incredible magnitude. As an example we may mention two shafts which were sunk through about 400 feet of the kind of ground in question at the Colliery Rheinpreussen, near Ruhrort in Germany. One, begun in 1857, was not finished after more than eighteen years' constant perseverance; while the other, begun in February, 1867, was only completed down to the solid ground in June, 1872.

The new method invented by Herr Poetsch is described by Bergassessor G. Kohler in the *Berg und Hüttenmännische Zeitung*, No. 38, xlii. *Jahrgang*, September 21, 1883. It consists in freezing the water contained in that portion of the running ground which occupies the position of the intended shaft into a solid mass of ice, and then sinking through it by hand without having to pump any water. To this end a preliminary shaft of larger dimensions than the intended shaft is sunk down to the natural level of the water. A number of vertical bore-holes about one metre apart are then put down round about its sides at the bottom, so that they pass through the ground just outside the lining of the intended shaft. Others are put down within the area of the intended shaft, and one is put down in its centre. All of these bores are continued down to the bottom of the running ground. They are made by means of the sand-pump, and are lined with sheet-iron tubes in the usual way. A circular distributing pipe with small copper tubes branching from it is placed at the bottom of the preliminary shaft. One copper tube extends to the bottom of each bore-hole, and each tube is provided with a stopcock. At the surface are several ice-making machines of the Carré type. The liquid intended to circulate through the bore-holes and effect the operation of freezing consists of a solution of the chlorides of magnesium and calcium, whose freezing-point lies between – 35° C. and – 40° C. By means of a small force-pump it is made to circulate at such a rate that it leaves the cooling-trough with a temperature of about – 25° C. It descends into the distributing pipe, passes through the copper tubes to the bottom of the bore-holes, ascends outside the copper tubes to the top of the bore-holes, finds its way into a collecting-tube, reascends to the surface, passes through the cooling-trough, and then commences the downward journey again.

Herr Poetsch estimates that, under ordinary conditions —that is, when the outer ring of bore-holes can be made in the ground outside the lining of the intended shaft— the freezing process will occupy from ten to fourteen days.

When it has been ascertained by means of bore-holes that the wall of ice round about the intended shaft is thick enough, the operation of sinking is commenced. The ice is cut out by hand, and a descending cylinder of masonry or iron is carried down at the same time. The lining prevents the surrounding ice-wall from breaking inwards, and the bottom cannot burst upwards.

Herr Kohler made a personal inspection of this process at the shaft Archibald now being sunk to the lignite beds at Schneidlingen, in Germany. The shaft passes through a bed of running sand four metres thick. Twenty-three bore-holes were employed in two rows near its sides. The freezing process was completed on August 10 last, when the running sand had become a compact mass of such great hardness that no impression could be made on it by the finger-nail, and it was with considerable difficulty that a flake 15 mm. thick could be broken from it.

Sufficient data do not yet exist for estimating the cost of this process as compared with those already known, but we are of opinion that if the operation of freezing can be effected in two or three weeks, or even months, it will compare favourably with them in this respect under almost any circumstances. We believe also that it is capable of application under a variety of circumstances not mentioned in Herr Kohler's article, such as damming back an excessive flow of water in solid ground, driving horizontal drifts or tunnels through mud and sand, and so on. We would therefore recommend the inventor rather to turn his attention in this direction than to think of condensing the intake air of mines by the application of cold, with the view of dispensing with ventilating furnaces and enabling winding operations to be carried on in upcast as well as in downcast shafts. The former field, if we mistake not, will be a large one; the latter, we can safely promise him, will be a very small one.

WILLIAM GALLOWAY

NORDENSKJÖLD'S GREENLAND EXPEDITION

IN a series of letters to Mr. Oscar Dickson, Baron Nordenskjöld has given a detailed report of the leading incidents and results of his recent expedition, though it will still be some time ere we can learn what are the full gains to science. The leading novelty of the expedition was, of course, the journey into the interior of Greenland. We have already given some account of Dr. Nathorst's visit to the Cape York region, and in the present article will confine ourselves mainly to Nordenskjöld's own journey up the interior. We reproduce a sketch map of this journey, which Mr. Dickson has been good enough to send us. After mentioning his attempt to approach the south-east coast of Greenland, Nordenskjöld says:—

> The ice much resembled the big rough blocks which are encountered north of Spitzbergen. The surface here carries a cold current which sets the ice on shore. The polar current is however not very voluminous; thus in a depth of a couple of fathoms Herr Hamberg discovered, through careful survey, a decided warm current from the south. The depth of the sea was not great, and the bottom consisted of large blocks which tore the trawling net and prevented dredging.

After landing Dr. Nathorst and his party at Waigatz Sound, Nordenskjöld went back to Egedesminde, which he reached on June 29. He then proceeds:—

> The following day I left for Auleitsivik Fjord, from which my expedition was to start. This fjord is about 130 kilometres long, and very narrow in the middle, not unlike a river, which widens at the bottom into a bay, Tessiusarsoak, into which an arm of the inland ice shoots. This remarkable formation, and the great tides which favour this part of Greenland, make the navigation here very difficult. As in most of the Greenland fjords the sea is deep and free from reefs. A remarkable feature, too, is that icebergs coming athwart the narrows in the fjord cause the water in the bay suddenly to rise some ten to twenty feet. The Esquimaux relate that some years ago a boat with men, women, and dogs was drawn under here by the whirl currents. They are, in consequence, afraid of rowing in the narrows.
>
> In 1870 I had paid a visit to this fjord and examined these difficulties, which I believed would have increased rather than otherwise during the last thirteen years, through those changes which so often occur in the position and size of the moving glaciers which shoot down from the inland ice. On inquiry I was told that no European had been in the fjord since 1870. Still my knowledge of

the feasibility of getting at least some 50 kilometres inland from this spot decided me to select it as my *point d'appui*.

On July 1 the *Sophia* anchored in the bay just north of the inland ice. We found here a splendid harbour with clay bottom, some seven fathoms deep, surrounded by gneiss rocks from 600 to 1000 feet in height, the sides of which are in some places covered with low but close shrubs, or clothed with some species of willow, mosses, and lichen, which, when we arrived, were ornamented with a quantity of magnificent blossoms. From one of the slopes a torrent descended, the temperature of which was 12°·3 C. The weather was fine, the sky cloudless, and the air very dry. July 1 to 3 were employed in making preparations for the ice journey, while the naturalists made excursions to various places in order to collect objects relating to the conditions of the country. On the night of the 3rd everything was ready for a start, and after some difficulty in reaching the spot where the baggage was we were fairly off. The spot from which we set out on the journey was only five kilometres from the actual shore, and situated below a little lake into which a number of glacier rivers fell. We proceeded up the river in a Berton boat purchased in England. On the night of the 4th we camped for the first time on the ice. The expedition consisted of nine men besides myself. After a great deal of hard work in getting the sledges over the ice, which was here very rough, we found on the morning of the 5th that it was impossible to proceed eastwards, but were compelled to return to the border of the ice and then continue to the north or north-east until finding smoother ice. This first part of the ice was furrowed by deep crevasses and ravines, causing us much trouble. We covered, however, a good distance that day, and pitched our tent near a land ridge in the ice 240 m. above the sea.[1] On July 6 I sent the Lapp Lars forward to reconnoitre, and he reported that it was still impossible to proceed eastwards, but if we marched for a day or so to the north we would find the country accessible to the east. As I feared, however, the impossibility of dragging the sledges with the weight on them over the rough ice, I selected provisions, &c., for forty-five days and left the rest in a depot in the ice. We now resumed the march. It was very interesting to witness the great ease with which the Lapps proceeded among the ice ravines, how easily they traced a road discovered, and with what precision they selected the least difficult track.

The Lapp Lars carried, instead of an alpenstock, a wooden club, with which he had slain more than 25 brown bears, full of marks from their teeth, and his eyes sparkled at the thought of encountering a white one. On the night of the 6th we held our third camp on the ice, and now several officers and men from the *Sophia*, who had accompanied us thus far, left us. Besides the most advantageous requisites for such a journey, we had with us a cooking apparatus for petroleum, and here I beg to say that I found this kind of oil far more suitable than train or vegetable oils, which I had used on my former expeditions, and I recommend the same most warmly to Arctic explorers. Of scientific instruments I may mention compasses, two chronometers, a circle by Pistor and Martin, a small sextant, in case of the former being damaged, a mercury horizon, three aneroid barometers, thermometers, magnets, for the study of the clay deposit in the snow, a topographical board, a photographic apparatus, blowpipes, flasks, nautical tables, &c. The sledges "kalkar," six in number, were of the same kind as those on which Swedish peasant women bring their wares to market; the harness was made so strong that it would hold a man in case of his falling into a crevasse. In addition to these things we had a manilla rope specially spun for the expedition at the Alpine purveyor's in Paris. The food supplied per day may perhaps interest explorers. It was—breakfast: coffee, bread, butter, and cheese (no meat or bacon); dinner; 42 cubic c.m. Swedish corn brandy (*bränvin*), bread, ham or corned beef, with sardines; supper: preserved meat, Swedish or Australian. Sometimes preserved soup was served with dried vegetables. Five men were teetotalers, but there was no need of supplying them with extra rations. For cooking, 0·7 litres of spirits were consumed per day. Our whole baggage weighed a ton, a weight which might easily have been drawn across a smooth snow or ice field, but which was very difficult of transporting over the rough and cut-up surface we had to traverse. Our daily march, between July 7 and 9, was, therefore, not great, viz. 5 kilometres a day. In addition to the crevasses and ravines, we encountered innumerable rivers, swift, and with steep banks which were difficult of crossing, which was generally accomplished by laying three alpenstocks across them. If I had not selected these of the toughest wood obtainable, we should often have had to make detours of many kilometres.

On these days we found on several occasions large bones of reindeer on the snow, and it was but a natural and pardonable conclusion to arrive at, that they were those of animals who had fallen in their wandering over the "Sahara of the Arctic regions." But that good signs are not always true ones we soon discovered.

During the entire journey we had great difficulty in finding suitable camping places. Thus either the ice was so rough that there was not a square large enough for our tent, or else the surface was so covered with cavities, which I will fully describe later on, that it was necessary to pitch it over some hundred smaller, and a dozen larger, round hollows, one to three feet deep, filled with water, or else to raise it on a snow-drift so loose and impregnated with water that one's feet became wet even in the tent. An exception to this was the place where we camped on July 9, viz. camping-place No. 6. We encountered here a small ice-plain, surrounded by little rivers, and almost free from cavities, some thirty metres square. All the rivers flowed into a small lake near us, the water from which rushed with a loud roar through a short but strong current into an enormous abyss in the ice plateau. The river rushed close to our tent, through a deep hollow, the sides of which were formed of magnificent perpendicular banks of ice. I had the spot photographed, but neither picture nor description can give the faintest idea of the impressive scene, viz. a perfectly hewn aqueduct, as if cut by human hand in the finest marble, without flaw or blemish. Even the Lapps and the sailors stood on the bank lost in admiration.

At first we had followed the plan of bringing the baggage forward in two relays, but, finding this very fatiguing, I decided to bring all with us at once. I found this to answer better. On July 10 we covered thus nine and a half, on the 11th ten, and on the 12th eleven, kilometres. The road was now much better than before, although stiff enough. An exception to this was, however, formed by the part we traversed on the 11th, when we proceeded alongside a big river, the southern bank of which formed a comparatively smooth ice plain, or rather ice road, with valleys, hills, cavities, or crevasses, some five to ten kilometres in width, and five kilometres in length. This plain was in several places beautifully coloured with "red" snow, especially along the banks of the river. It was the only spot on the whole inland ice where we found "red" snow or ice in any quantity. Even yellow-brown ice was seen in some places, but, on the other hand, ice coloured grayish-brown or grayish-green, partly by kryokonite, and partly by organisms, was so common that they generally gave colour to the ice landscape.

---

[1] The altitudes were ascertained by comparing three aneroid barometers, while observation was simultaneously made at Egedesminde with a splendid sea barometer I had left there for that purpose. As the figures have, however, not yet been verified, they may be slightly altered. They seem on the whole too low.

Even on July 12—between camps Nos. 7 and 8—we found blades of grass, leaves of the dwarf-birch, willows, crackberry, and pyrola, with those of other Greenland flora, on the snow. At first we believed they had been carried hither from the interior, but that this was not the case was demonstrated by the circumstance that none was found east of camp No. 9. The only animals we discovered on the ice were, besides the few birds seen on our return journey, a small worm which lives on the various ice algæ, and thus really belongs to the fauna of the inland ice, and two storm-driven birds from the shore. I had particularly requested each man to be on the look-out for stones on the ice, but after a journey of about half a kilometre from the ice border no stone was found on the surface, not even one as large as a pin's point. But the quantity of clay dust ("kryokonite") deposited on the ice was very great; I believe several hundred tons per square kilometre.

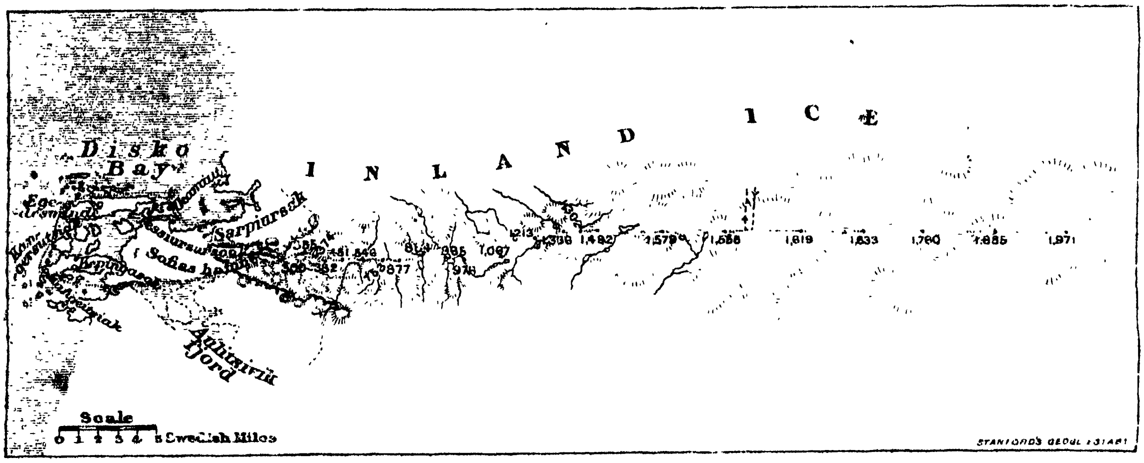
We now ascended very rapidly, as will be seen from the subjoined statement of our camps:—

3rd camp, 300 metres above the sea.
4th " 355 " "
5th " 374 " "
6th " 382 " "
7th " 451 " "
8th " 546 " "
9th " 753 " "

The 9th camp lay on the west side of an ice ridge close by a small, shallow lake, the water from which gathered as usual into a big river, which disappeared in an abyss with azure-coloured sides. From this spot we had a fine view of the country to the west, and saw even the sea shining forth between the lofty peaks on the coast; but when we reached east of this ice ridge the country was seen no more, and the horizon was formed of ice only.

Through an optical illusion, dependent on the mirage of the ice horizon, it appeared to us as if were proceeding on the bottom of a shallow, saucer-shaped cavity. It was thus impossible to decide whether we walked up or down hill, and this formed a constant source of discussion between us, which could only be decided by the heaviness of the sledges in the harness. The Lapps, who seemed to consider it their sole business that we should not be lost on the ice, came to me in great anxiety and stated that they had no more landmarks, and would not be responsible for our return. I satisfied them, however, with the assurance that I would find the way back by means of a compass and solar measurements. In spite of this the Lapps easily traced our route and our old camps with an accuracy quite marvellous.

During our outward journey I determined the site of each camp astronomically, and thus the distances which, when the determinations have been calculated, will be given on the map to be drawn of the journey will be absolutely correct. But the distances covered by the Lapps have been made according to their own judgment. The kilometres we covered every day, including the numerous detours, were ascertained by two pedometers.



The heights are given provisionally in metres. Swedish mile = 6·64 English miles.

Up to the 9th camp we were favoured by the finest weather, generally with a slight south-east wind, cloudless sky, and a temperature in the shade, three feet above the ice, of 2° to 8° C., and in the sun of even 20° C. The centre of the sun's disk sank in this spot for the first time below the horizon on July 15, and the upper rim, if allowance is made for refraction, on July 21. After the middle of July, when at an elevation of 4000 to 7000 feet, the nights became very cold, the thermometer sinking to 15° and 18° below freezing-point of Celsius.

The constant sunshine by day and night, reflected from every object around, soon began to affect our eyes, more so, perhaps, because we had neglected to adopt snow-spectacles at the outset of our journey, and snow-blindness became manifest, with its attendant cutting pains. Fortunately Dr. Berlin soon arrested this malady, which has brought so many journeys in the Arctic regions to a close, by distributing snow-spectacles and by inoculating a solution of zinc vitriol in the blood-stained eyes. Another malady—if not so dangerous, at all events quite as painful—was caused by the sunshine in the dry, transparent, and thin air on the skin of the face. It produced a vivid redness and a perspiration with large burning blisters, which, shrivelling up, caused the skin of the nose, ears, and cheeks to fall off in large patches. This was repeated several times, and the pain increased by the effect of the cold morning air on the newly-formed skin. Any similar effect the sun has not in the tropics. With the exception of these complaints none of us suffered any illness.

On July 13 we covered thirteen, on the 14th ten, and the 15th fourteen, kilometres (9th to 12th camps). At first the road gradually rose, and we then came to a plain which I in error believed was the crest of the inland ice. The aneroids, however, showed that we were still ascending: thus the 9th camp lies 753, the 10th 877, the 11th 884, and the 12th 965 metres above the sea. Our road was still crossed by swift and strong rivers, but the ice became more smooth, while the kryokonite cavities became more and more troublesome. This was made more unpleasant by rain which began to fall on the afternoon of July 13, with a heavy wind from south-east. It continued all the night, and the next morning turned into a snowstorm. We all got very wet, but consoled ourselves with the thought that the storm coming from south-east argued well for an ice-free interior. When it cleared a little we strained our eyes to trace any mountains which would break the ice horizon around us, which everywhere was as level as that of the sea. The desire soon "to be *there*" was as fervent as that of the searchers of the Eldorado of yore, and the sailors and the Lapps had no shadow of doubt as to the existence of an ice-free interior. And at noon, before reaching camp No. 12, everybody fancied he could distinguish mountains far away to the east. They appeared to remain perfectly stationary as the clouds drifted past them, a sure sign, we thought, of its not being a mass of clouds. They were scanned with telescopes, drawn, discussed, and at last saluted with a ringing cheer. But we soon came to the conclusion that they were unfortunately no mountains, but merely the dark reflection of some lakes further to the east in the ice desert.

A. E. NORDENSKJÖLD

(*To be continued.*)

THE RE-ENTOMBMENT OF WILLIAM HARVEY

FOR two hundred and twenty-six years the mortal remains of the immortal discoverer of the circulation of the blood rested, unburied, in a vault of a little church in the parish of Hempstead, about seven miles from Saffron Walden, in Essex.

Harvey died on the 3rd of June, in the year 1657, being then in his eightieth year, but the precise place of his death is not known. He fell, full of days and honours, and retained his faculties so completely to the last day of his life that he directed his apothecary, Samboke, what to do in the way of treatment. He beckoned to Samboke to take blood from under the tongue as the speech was failing,—a line of treatment which would have little favour in these days,—and as the sun of June 3 went down he went down also. His death, no doubt, took place in London, and probably near to Smithfield.

On June 26, twenty-three days after the death, the body of William Harvey was laid in the vault at Hempstead. In the interval a cast had been taken from the face for a rough and ready sculptor to work from, and the body, after a custom of the time, rolled first, in all probability, in a cere cloth, had been inclosed in a leaden chest. It was then conveyed to Hempstead, a distance of about fifty miles, in those days a journey of no slight importance. The body was followed by many of the Fellows of the College of Physicians out of town, and it may be that some of them went as far as Hempstead. Certainly one scholar, though he was not a Fellow, namely Aubrey, the historian, was present when the body was put into the vault. "I was at his funeral, and helpt to carry him into the vault." These are Aubrey's words. The vault referred to had been built by Eliab, the merchant brother of the anatomist, and over it was erected a chapel connected with the church at the north-eastern corner. The vault was afterwards filled with the bodies of members of the Harvey family, some few "lapt in lead," like their great relative, others laid in coffins.

For nearly two centuries little seems to have been recalled of the remains of the anatomist. They lay with their kindred in the village sepulchre without reference being made to them. In 1847 Dr. Richardson, F.R.S., then assisting Mr. Thomas Browne, a surgeon in Saffron Walden, was told one day by a cottager that the great Dr. Harvey was buried in Hempstead Church, and next day discovered that it was really Harvey the anatomist and physiologist, and that the body, "lapt in lead" as Aubrey described, lay there probably as it had originally been placed.

At that time the foot of the leaden chest lay under the open window of the vault. There was then no opening in the lead, but the upper surface towards the middle of the body was beginning to show signs of sinking in. There was much dust and several stones on the chest, which were removed. The remains were reported upon after this by Dr. Tyler Smith, who had visited the place, to the Royal College of Physicians, and in 1859 the College deputed the late Dr. Alexander Stewart and Dr. Quain to visit and report. They made their report, and some changes were carried out in the vault; but the window, although protected by the addition of iron bars, was left open, and, under the influence of air and damp, the lead began to give way.

From time to time Dr. Richardson visited the place and reported on the changes which were in progress. In the lower part of the lid of the leaden chest the sinking became so increased that a kind of oblong basin was formed, in which rain water, beating in from the window, accumulated. Then an opening, taking the shape and size of one of the sound openings in a violoncello, was formed, and water was admitted into the shell itself. Twice it seemed filled with thick pitchy-looking fluid, and although the opening was temporarily filled up with solder, the repair did not last very long.

In 1878 Dr. Richardson made another visit to Hempstead, and on November 30 of that year published in the *Lancet* a full report on the condition of the remains, together with six illustrations. The report created considerable attention, and led the way to the alteration that has been recently effected. In January, 1881, the beautiful tower of the old church at Hempstead suddenly fell, dragging a portion of the church with it. It was found that the Harvey vault and chapel were not injured, but that the leaden shell in which Harvey was laid was again filled with water, and that the preservation of the case could not be much longer insured. In February, 1882, the Royal College of Physicians, formed a committee to undertake the duty of placing the remains in a position in which they would be permanently retained. The result was that the College obtained permission of the representatives of the Harvey family to remove the remains from the vault and to place them in a solid marble sarcophagus in the Harvey chapel above. Such is a succinct history of the proceedings previous to the removal and re-entombment on October 18 of this year.

The ceremony of the 18th was extremely simple. As was befitting, a number of the Fellows of the College—eight in all—bore the remains from the vault along the northern side of the church to the western entrance, and so through the aisle to the entrance of the Harvey chapel, on the left of the chancel. The vicar of Hempstead, the Rev. R. H. Eustace, and the curate, the Rev. J. Escreet, led the procession; then came the bearers with their charge on a bier; after them, four of the representatives of the Harvey family; and, next in order, the President, all the office-bearers, and the Fellows of the Royal College of Physicians who had come to take part in the ceremonial.

After a short service the leaden case was placed in the sarcophagus. On the breastplate of the case the original inscription—

Doctor
William. Harvey
Decesed. The. 3.
Of Jvne 1657.
Aged 79 years

was still quite perfect, as was also a rough metal cast of a face with a small imperial from the lower lip to the chin. After the remains had been laid in the marble, the President of the College, Sir William Jenner, placed on them a leaden case containing the College edition of the complete works of Harvey. The volume was the Latin edition of 1766, edited for the College by Mark Akenside, including in the first pages a life of the illustrious anatomist and discoverer. Together with this volume there was also put into the sarcophagus a memorial bottle cased in lead and containing various details relating to the removal. The bottle included views of the church, before and after the fall of the tower, executed on wood; a description of the church and the vault, and the time the remains had been in the vault; several photographic views of the church; a beautiful photograph of the bust of Harvey; a scroll of vellum on which was engraved a description of the reasons why the remains had been put into the marble, with the names of all who had taken part in the ceremony; and a printed account of the proceedings that were carried out at the second interment on October 18th, 1883. The sarcophagus was then finally closed by rolling on and cementing down the massive cover or lid. On the western side of the sarcophagus is engraved the following:—

THE REMAINS OF WILLIAM HARVEY,
DISCOVERER OF THE CIRCULATION OF THE BLOOD,
WERE REVERENTIALLY PLACED IN THIS SARCOPHAGUS
BY THE ROYAL COLLEGE OF PHYSICIANS OF LONDON
IN THE YEAR 1883.

At the foot are inscribed the words,

WILLIAM HARVEY.
BORN 1578. DIED 1657.

NOTES

WE are glad to learn that M. Dumas is much better, though it is probable he will have to spend the winter in the south of France.

THE arrangements for beginning work at Ben Nevis Observatory will be completed this week, and Mr. Omond will take up his post on the summit in the middle of next week, when observations will be at once begun. The telegraph cable has now been completely laid.

THE Fisheries Exhibition was closed yesterday with much ceremony; its success as a popular exhibition is almost unprecedented, and, as we have pointed out in several articles, some of the exhibits have been of real scientific value.

WE regret to announce the death, last Saturday, of M. Breguet, the well known electrician, member of the French Institute and of the Bureau des Longitudes. M. Breguet's second son, a promising electrician, died about twelve months ago, and was deeply regretted. The death of M. Breguet has been all the more noticed that a few days ago the death of M. Niaudet-Breguet, his nephew, was announced. M. Niaudet-Breguet was also devoted to electricity. The well-known Breguet firm will not be extinguished by these multifarious losses, having been made lately a joint stock company. It is one of the oldest in Paris, having been established in 1783.

THE arrangements for the International Forestry Exhibition which is to be held in Edinburgh next year have been settled. The classification of the exhibits ranges over a wide and interesting field. Practical forestry will be illustrated by implements, models of huts, appliances for floating and transporting timber, and wood-working machinery of every description. The department of forest produce will include a collection of the chief uses to which the raw and the manufactured material of the woods may be applied. The class of scientific forestry will deal with the botany of the forests, forest entomology, preservative processes applied to timber, fossil plants, parasites, and numerous other subjects. Growing specimens of rare and ornamental trees and shrubs, rustic work in arbours, bridges, gates, and seats, and dried specimens of ornamental objects will exemplify the division of ornamental forestry. The remaining departments will include pictorial illustrations of the trees, foliage, and scenery of all countries, and the effects of blight, accident, parasitic growth, and abnormal conditions, together with the literature of forestry, working plans of plantations, and examples of the economic condition of foresters and woodmen. The entries for the Exhibition will close on October 4, 1884.

LAST Thursday, October 28, the three classes of the French Institute held their annual meeting. The addresses were delivered this year by the members of other classes than the Academy of Sciences. In the evening the members of the Institute held a great banquet by subscription among themselves. This is the first time that the annual meeting has been so solemnised.

THE seventh International Geodetic Conference terminated its labours on October 24, when the acting president, Col. Ferrero, proclaimed the result of the new election of the permanent committee, as follows:—Lieut.-General Ibanez, Director-General of the Geographical and Statistical Institute, Madrid, President; Col. Ferrero, President of the Italian Geodetic Commission, Vice-President; and Dr. Hirsch, Director of the Observatory at Neuchâtel, and Dr. von Oppolzer, Professor of Astronomy at the University of Vienna, Secretaries. Prof. Bauernfeind read his report on refraction, which was followed by a proposal, made by Major Hartl, and approved, to the effect that the Conference expressed a hope that all the European States represented in the Association would institute thorough investigations into terrestrial refraction, in order to ascertain the influences which the different characteristics of the ground and of the climate exercise upon refraction. Prof. Schiaparelli, Director of the Observatory at Milan, read the report of the special committee named to consider the proposal made by Prof. Fergola regarding systematic observations of latitude, with the intent of verifying the stability of the terrestrial axis of rotation, and ascertaining the movements of the poles; which report, after some discussion regarding the manner in which the observations should be carried out, was approved.

BARON NORDENSKJÖLD has, in consequence of the attacks which have been made in foreign journals in connection with the unfortunate *Dijmphna* expedition, on his theory as to the navigability of the Kara Sea, telegraphed to Lieut. Hovgaard inquiring whether he considered it would have been possible to reach the Yenisei this summer. Lieut. Hovgaard replied that he was fully convinced that had he been prepared to proceed he could easily have reached Siberia this autumn, and further points out that he could have done so last year also had he not, by signals of distress from the *Varna*, been compelled to leave the lead along the shore of the Waigatz Island, which was open as far as the eye could reach, and enter the pack ice where he was frozen in.

IN No. 3, vol. vi. of the *Deutsche Geographische Blätter* is an article by Prof. Börgen, in which he discusses the objects proposed and the theories entertained by Nordenskjöld in connection with his expedition to Greenland. The paper was written before the expedition left. Dr. Börgen adduces some particulars which make him incline to the supposition that the watershed of Greenland lies rather towards the east than the west. In any case, in consideration of the comparatively short distance of any part of Greenland from the sea, and of its low average temperature, Dr. Börgen argues that winds both from the east and the west must deposit snow everywhere on the weather side of the mountains against which they strike, and so maintain the conditions for the formation of glaciers. These glaciers, again, must in the course of time drift down into the valleys and the lowest levels, the temperature of Greenland even down to the level of the sea being everywhere below the freezing-point. This view is further supported by ascertained facts and by conclusions drawn from the direction of the winds, as given in Coffin's work, "The Winds of the Globe." The article in other respects communicates important details and arguments regarding the geography of Greenland.

THE Association Internationale Africaine has been so satisfied with the services of the Swedish officers who assist Mr. Stanley in his exploits on the Congo, that four more, who have volunteered their services, have been engaged, and will leave Europe on November 15. We announced some time back that the Royal Geographical Society of Sweden had conferred the *Vega* medal, the greatest honour at the disposal of the Society, on Mr. Stanley. At the last meeting of the Society the President, Dr. Montelius, read a letter received from the explorer, dated Stanley Pool, in which he thanked the Society for the great honour conferred on him.

THE last number of the *Izvestia* of the East Siberian Geographical Society contains a valuable paper by MM. Agapitoff and Khalganoff, on the Shamanism of the Balagansk Buriats of the province of Irkutsk; several letters from the Lena Meteorological Station (already noticed in NATURE), with a plan of the station; meteorological observations made at Markha in August and September, 1882, and at Magan (ten miles to the north-west of Yakutsk), from July, 1882, to March, 1883; and a paper on the settlements of the 14,000 Chinese, Mantchous, and Dahours, who have remained under Chinese rule, although settled on the left bank of the Amur, at and below its confluence with the Zeya. We notice in this paper that during the three great summer inundations of 1881, the level of water in the Amur, one mile wide at this place, and the Zeya 1·3 mile wide, rose as much as 19 feet in a few days, and that the whole change of level of the Amur was, during the summer, as much as 28 feet. This figure, although much below those which are found for the Amur below its confluence with the Sungari, and exceeded during the inundations of 1872, gives some idea of the mass of water poured on the Pacific slope of the great Siberian plateau during the season of the summer rains.

AN interesting relic of the past has just been unearthed in the parish of Pulborough, Sussex, in the shape of a canoe, which was partly embedded under the River Arun, and partly in land on the south side of that river. The boat is of solid oak, and hewn from a single massive trunk. That it was made before the knowledge of metal is evident, as there is not a trace of building or planking. It must have been hollowed by means of the stone axe and of fire. Further evidence in favour of the antiquity of this boat appears to be afforded by the various accumulations which had formed over that portion of it which was embedded in the earth. These strata, to the depth of nine feet, have been ascertained to be loam, yellow clay, a thin layer of leaves, followed by a stratum of blue mud, beneath which lay the boat embedded in drift sand. The prow portion of the boat lay in the river, and this is by far the most dilapidated. The stern is comparatively intact. The present dimensions of the boat are fifteen feet by four feet; but originally it was probably eighteen feet long.

ON Monday, September 24, about 9 p.m., a remarkable phenomenon occurred at Käringön, in the province of Bohus, Sweden. During a perfect calm a violent whirlwind suddenly arose from the south-east, carrying with it a quantity of sand, earth, and straw, when suddenly a bright light lit up every object and made the night as clear as day. This was caused by a magnificent meteor, egg-shaped in form, which appeared in the zenith, and which at first seemed to consist of myriads of large sparks, gradually changing into a star shining with a blinding lustre, and which burst, with all the colours of the rainbow, in the north-west, four to five metres above the horizon. When the meteor had disappeared the wind suddenly fell, and it was again perfectly calm. The phenomenon lasted about sixty seconds. The wind had throughout the day been south and very slight.

DR. MEYER asks us to state that in our note on his paper on jadeite the name *Montevideo* should be *Monteviso*, and he thinks it better, to avoid misunderstanding, to use *jadeite* instead of *jade*. Moreover, the material from Monteviso is only doubtfully jadeite. At Suckow, Uckermark, only one piece was found, but this is the fourth "in North Germany." "At the same time," Dr. Meyer writes, "I take the liberty of drawing the attention of your readers to Prof. Arzruni's recently-published paper on the jade question in the Berlin *Zeitschrift für Ethnologie*, pp. 163-190. The mineralogist of Breslau comes to the same conclusion as myself, *i.e.* that the raw materials were *not* imported from Asia; and the chief reason upon which he relies is that he found the nephrite and jadeite varieties from the different localities to possess *typical* microscopical differences. This alone would suffice to put aside the importation hypothesis. I discovered last September in Graz, Styria, a boulder of nephrite from the alluvium of the river Mur, and shall soon send you a separate copy of the paper which I am about to publish on the same."

A PALÆOLITHIC implement of large size was found a week or two ago by Mr. G. F. Lawrence, of 49, Beech Street, in gravel excavated in the Clerkenwell Road, near the Sessions House. The implement weighs 1 lb. 3 oz., and is slightly larger than the historical implement found near Gray's Inn Lane at the close of the seventeenth century, and now in the British Museum.

A SHARP shock of earthquake was felt at Bermuda on October 20, but no damage was done. A shock was felt at Tashkend at twenty minutes past two on the morning of the 27th, accompanied by loud subterranean rumblings. A despatch from Smyrna dated October 28 reports that the wall surrounding the town, the Aqueduct, and the Hadji Hussein Mosque have been damaged by an earthquake. The minaret and dome of the Hadji Ali Mosque at Capan Vourla have also been injured. At the last-named town one hundred and sixty-nine persons have been seriously, and sixty-one slightly, hurt. Seventy-nine wounded people are in the hospitals.

A ROMAN city has been discovered in Tunis by Lieut. Massenat, who lately accomplished a scientific mission in the vicinity of Bograra (Gulf of Gabes). This city is said to be located in the southern part of Djerba. The circuit of the ruins is about three kilometres.

AN extraordinary case of subsidence has been observed in the vicinity of Bone. The Naïba, an isolated mountain of 800 metres altitude, is gradually descending into the bosom of the earth. A deep excavation has been made all round, encircling the whole ingulfed mass.

WITH reference to our notice of "The Fishes of Great Britain and Ireland," last week (p. 611), Mr. Day wishes us to state that the work will be in two volumes, and that the parts published reach to p. 176 of the second volume.

THE additions to the Zoological Society's Gardens during the past week include a Striped Hyæna (*Hyæna striata*) from Morocco, presented by Mr. Ernest H. Marquis; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mrs. M. J. Mitchison; a Black Rat (*Mus rattus*), British, presented by Mr. Camp; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mr. S. J. W. Colman; a Kestrel (*Tinnunculus alau-*

darius), British, presented by Mr. T. E. Gunn; two Pintails (*Dafila acuta*), two Wigeons (*Mareca penelope*), European, presented by Mr. Charles E. Boultbee; a Margined Tortoise (*Testudo marginata*) from the Ionian Isles, presented by Miss Mansell; a Purple-faced Monkey (*Semnopithecus leucoprymnus* ♀) from Ceylon, a Pinche Monkey (*Midas œdipus*) from Brazil, two Common Marmosets (*Hapale jacchus*) from South-East Brazil, deposited; a Chimpanzee (*Anthropopithecus troglodytes* ♂), a Chimpanzee (*Anthropopithecus calvus*? ♀) from West Africa, a Chipping Squirrel (*Tamias striata*) from North America, two Bramblings (*Fringilla montifringilla*), European, purchased; two Simon's Dwarf Jerboas (*Dipodillus simoni*) from Arabia, received in exchange; six Long-nosed Vipers (*Vipera ammodytes*), born in the Gardens.

BIOLOGICAL NOTES

OBSERVATIONS ON THE EMBRYOLOGY OF THE TELEOSTS, by J. S. Kingsley and H. W. Conn. The observations were made during the summers of 1881 and 1882 at the Summer Laboratory of the Boston Society of Natural History at Annisquam, Mass., on the egg development of *Ctenolabrus cæruleus*. The eggs were obtained by surface skimming, and were usually equally abundant during the day and in the evening, and as a rule were more so on the flow than on the ebb of the tide. Half an hour's skimming would produce on an average 150 eggs. These eggs all floated at or near the surface of the water, and presented a marked contrast to those of either an Elasmobranch, Batrachian, Reptile, or Bird, in that the germinative portion is invariably downward or on the lower surface of the egg, while the deutoplasm is uppermost. The stages observed were: the maturation of the ovum, the phenomena of segmentation until the formation of the germ layers, the formation of the three primary layers, the segmentation cavity, the invagination of the hypoblast, and the appearance of nuclei in the intermediary layer of Van Bambeke, the formation of the notochord and neural cords, the former arising from the hypoblast at first as a longitudinal median thickening of that layer, and subsequently becoming segmented off and taking its place among the mesoblastic tissues, the development of the optic bulbs and protovertebræ.

EMBRYOLOGICAL MONOGRAPHS.—Under this title Prof. Alexander Agassiz proposes to issue a series of selections from embryological monographs, so as to give the student in an easily accessible form a more or less complete iconography of the embryology of each important group of the animal kingdom. It is not intended that these monographs should be handbooks to the subject, but rather act as atlases to accompany any general work on the subject. The plates will be issued in parts, each part covering a somewhat limited field, and occasional appendices may be published to prevent the plates from becoming antiquated. The illustrations will be accompanied by carefully prepared explanations, and by a bibliography of the subject in octavo. This work, planned out in 1873, has only now been matured. The first part is on the embryology of Crustacea, with fourteen plates, edited by Walter Faxon. The figures on these plates are taken from all the most reliable sources, and an important volume of bibliography accompanies the atlas. The parts devoted to Echinoderms, Acalephs, and Polyps are well advanced, and it is intended to figure the phenomena connected with fecundation and maturation and the history of the formation of the embryonic layers in a separate part, without regard to the systematic zoological connection of the observations.

CERATODUS FORSTERI.—Mr. Morton got twelve specimens of this fish in the Mary River, Queensland, one only in a net; all the others were trapped by the blacks by being forced through a narrow passage in the river formed by a kind of brushwood. He noticed a curious circumstance as regards their habits. At the time of his visit a number of Eucalyptus trees were in full flower by the banks of the river, and as the blossoms dropped into the water they were eagerly seized and swallowed by these fish. The stomachs of each of the specimens captured were literally crammed with these flowers. An old resident told Mr. Morton that during June to August these fish go in pairs, that they make slight indentations in the muddy bottom in from six to ten feet of water, in which the spawn is deposited, that the male and female fish remain near the spawn, and are not then easily disturbed, that they frequent the same place every year, and that the spawn is frog-like. He had taken it and hatched it in a tub of water, keeping the young alive for some weeks. (W. Macleay in *Proc. Lin. Soc. New South Wales*, vol. viii. part 2, July 17, 1883).

GLYCOGEN was lately found by M. Errera in fungi of the order Ascomycetes (before, it had only been observed in the animal kingdom and in Myxomycetes, organisms which naturalists have placed, sometimes among animals, sometimes among plants). Continuing his researches, he now finds the substance (*Bull. Belg. Acad.*, No. 11, 1882), not only in Ascomycetes, but in many Mucorineæ, such as *Phycomyces nitens*, *Mucor mucedo*, and *stolonifer*, *Pilobolus crystallinus*, *Chætocladium Jonsii*, *Piptocephalis Fresenianа*, *Synecephalis nodosa*. He has specially studied *Phycomyces nitens*, the large size of which is an advantage. In it the glycogen does not occur in localised masses, as in the *Asci* of Ascomycetes. When the mycelium filaments are young it is distributed throughout the protoplasm; later it is carried to the top of the cell which is destined to give rise to the sporangium. Its quantity does not diminish notably during formation of the sporangium, so it does not seem to have a preponderant *rôle* in growth of the membrane. It is found in the spores, and probably another portion serves for respiratory combustion; the rest may be utilised for growth of membranes of the sporangium-filament and the spores. Having got 40 grammes of dried *Phycomyces*, M. Errera extracted glycogen with all its reactions, confirming the results of micro-chemical analysis.

MARINE ZOOLOGICAL LABORATORIES[1]

[THE following communication has been forwarded to us by an eminent biologist, with the request that it be reproduced in our pages]:—

Nearly all the European States except England have on their sea-coast marine zoological laboratories; it may therefore, especially in view of the recent proposals of Prof. Lankester, and the manifesto of biologists which has followed it, perhaps be interesting to your readers to peruse the following description of these laboratories; they will then be able to appreciate their utility, indeed absolute necessity, in order to study or pursue investigations in certain branches of science.

These seaside laboratories, or *stations zoologiques maritimes*, have nearly all been founded by zoologists for the purpose of advancing zoological science. Fortunately they also help both students and scientists in other branches of science than that of zoology, the one to arrive at a proficiency of knowledge, the other to carry out interesting and valuable researches which, but for this brotherly help, would be impossible. The countless species of marine animals attract physiologists, histologists, and comparative anatomists to work in a field which may reveal facts hitherto undiscovered in that more limited area which is included in the study of terrestrial and fresh-water animals.

The success of these laboratories is doubtless increased by the fact that they are always in a healthy locality on a bracing seashore, so as to allow a realisation of the apparently anomalous combination of work and rest. The scientist, worn out by fatiguing researches made in town laboratories, finds fresh elements of health and a fresh field for research by passing three or four months at a seaside laboratory.

The first of this class of laboratory is the one founded at Naples by Herr Dohrn, a private enterprise almost exclusively German, which nevertheless has received substantial aid from the city of Naples, and some years hence will become the town property.

In order to work in the Naples laboratory a heavy fee is exacted. Nearly all the tables are retained yearly by different universities or scientific societies; the British Association has two tables. The revenue is greatly increased by the fees of admission to an aquarium of marine animals.

This laboratory is admirably organised; there is an agreement between the authorities and the fishermen that the latter shall take to the laboratory all rare animals that they may chance to find; likewise there is every necessary arrangement for dredging excursions and for diving into the depths of the sea to find such animals as are required for study. There are several sailing boats and a steamboat belonging to the laboratory, which is also well provided with diving dresses. The animals are kept in a large tank, which is large enough for specimens of considerable dimensions.

---

[1] From the *British Medical Journal*, October 13, "Special Correspondence, Paris."

France, apart from the laboratory of the Science Faculty at Marseilles, which has an aquarium and a boat, possesses five seaside laboratories. They are distributed as follows: one at Villefranche, superintended by M. Barrois; one at Banyuls, near Port Vendres, superintended by M. Lacaze Duthiers; another at Concarneau, on the south coast of Brittany, superintended by MM. Robin and Pouchet; another at Roscoff, on the north coast of Brittany, superintended by M. Lacaze Duthiers; and one at Havre, superintended by M. Paul Bert. Besides these principal establishments, there are two or three others, such as those of Arcachon and Lucques, which have been founded either by provincial scientific societies, or by professors who have received some slight aid from the corporations of the towns where these laboratories are established; but these laboratories possess neither special tenants, boats, nor sailors, therefore they are only of use to their founders and a limited number of pupils.

The laboratories of Villefranche, Roscoff, Concarneau, Banyuls, and Havre are founded and kept up by the French Government; in some cases the corporations have given money or granted land. The laboratories of Concarneau and Roscoff present two varieties widely different.

The laboratory at Concarneau is situated at the entrance to the port; it was founded by Coste, the well-known embryologist, who wished to study the different conditions attending the reproduction of marine animals. The building consists of two stories: the ground floor is used for the aquariums, three in number; on the first floor are the workrooms. The rocks facing the laboratory have been utilised, and are transformed into eight basins or reservoirs of water, each from 300 to 1200 feet square, and from 15 to 20 feet deep. The aquariums are filled with water by means of a pump set in motion by the wind. There is only one boat belonging to this laboratory, but the French Government always place a war sloop at the disposal of its director; this summer some of the laboratory workers wanted to dredge a long way out at sea, and the Government lent them a despatch-boat. The coast abounds in marine animals, but is poorer in invertebrates than that of Roscoff; it is more especially a coast for sardine fishing. The surrounding scenery is lovely.

Roscoff perhaps offers greater advantages, though fewer attractions. Cabbage-fields and tracts of land devoted to the cultivation of artichokes, though a proof of the mild and delightful climate of this little seaport, are by no means an acceptable substitute for the beautiful scenery of Concarneau, but the treasures of the sea here, more abundant than on the coast of Concarneau, or indeed on any other part of the whole French coast, are ample consolation to the crowd of workers who annually avail themselves of the facilities for studying and carrying out researches which the Roscoff laboratory, founded by M. Lacaze Duthiers, affords them free of cost.

The coast of Roscoff offers peculiar advantages for a seaside laboratory, or, in French terminology, *station zoologique maritime*. The numerous boulders of granite serve as places of shelter for the neighbouring marine animals. It also presents a vast expanse of sand sea-shore and a large bay of slime, thus all the different kinds of marine animals are within reach.

Notwithstanding these remarkable qualifications which M. Lacaze Duthiers quickly detected, he had considerable difficulty to get a footing for his laboratory. It now consists of a large house bought by Government, to which has been recently added the village schoolhouse (*École Communale*), abandoned, since education has become compulsory, for another affording increased accommodation. A third house, opposite to the one bought by Government, is hired for the convenience of the laboratory workers. It must be remembered that Roscoff is only a little fishing village, and it is often difficult to find a room during the summer season, therefore M. Lacaze Duthiers offers a bedroom to all who work in his laboratory.

There are two sailors belonging to the laboratory; and one of the attendants from the Sorbonne laboratory is on duty at Roscoff during the summer months. The garden of the laboratory reaches down to the sea. A large reservoir, measuring 4200 feet, has been constructed, where are kept marine animals, either at liberty or in cases. On a small island opposite the laboratory there is a "bed" where animals of sedentary habits are kept almost at liberty.

The laboratory has three sailing boats adapted for taking excursions among the rocks and on the neighbouring shores, also for dredging either with the usual drag, oyster-drag, or with a coral-fishing apparatus. The fishermen also take a considerable quantity of marine animals to the laboratory.

This Roscoff *station zoologique maritime*, which M. Lacaze Duthiers had so much trouble to found, is now in its fifteenth year. The French Government by degrees added to its local habitation, which, if even at the present time not perfect, is nevertheless of immeasurable utility to scientific workers, and therefore contributes to the progress of science.

The Roscoff laboratory is perhaps more frequented than any other, and is an enduring testimony to the patience and laudable determination of its founder and director. The expenses are defrayed from the fund annually voted by the French Parliament for public instruction. Here, as in all establishments in France for higher education, no fees are paid; but this success was hardly won; the necessary sum was with difficulty wrung from the Government, and the local authorities, notwithstanding the evident advantages such an establishment brings to the village, were equally tardy to grant the concessions eventually obtained, unlike those of Banyuls, who conceded a building site, also a yearly revenue, and subsequently presented the laboratory with a boat.

The most recently organised seaside laboratory is at Havre; the building it occupies was formerly a public aquarium, which the corporation handed over to M. Paul Bert. It is supported from Government and corporation funds, and is more especially destined to facilitate physiological research. Doubtless, when the arrangements now in course of completion are perfected, they will offer all the requirements for studying this branch of science, a qualification evidently all but absent in laboratories founded by zoologists.

It must be admitted that all these seaside laboratories, or *stations zoologiques maritimes*, taken both separately and in the aggregate, render important service to biologists of all nations. Every year there is a large percentage of foreigners among the workers, the English element bearing always the largest proportion, a proof that our countrymen fail to appreciate their good fortune in possessing a more extensive sea-coast than that of any other country, or they would be able to offer this useful form of hospitality as well as seek it. Nevertheless, considering the scanty encouragement given by the public and the English Government to biological science, it is to be feared that many years will pass by before *stations zoologiques maritimes* exist on the English coast.

The only similar laboratory in Holland belongs to the Universities of Utrecht and Leyden. The Dutch coast is not rich enough in marine animals to suggest the advisability of establishing many zoological laboratories, therefore a movable or migratory laboratory has been organised, which consists of a wooden house, easily taken down and put up again; there are three rooms in it, a large workroom, and two smaller ones used for the aquarium and fishing apparatus. At the beginning of every summer it is set up on the coast on a piece of land hired for the purpose, or more frequently lent by the nearest village; thus the Dutch scientists visit the entire coast, study its marine animals, and even that of their neighbours. Russia has a laboratory on the Black Sea, and Austria possesses one at Trieste.

In connection with the above communication, we may state that Mr. Romanes writes to Tuesday's *Times* forcibly pointing out the need of a thoroughly equipped zoological station on the British coast, and its value both to science and to our fisheries. Referring to the recent manifesto, so influentially signed, printed in our columns, Mr. Romanes hopes the executive committee will see their way to adopting its suggestions.

THE ASSOCIATION OF GERMAN NATURALISTS AND PHYSICIANS

THE fifty-sixth annual meeting of this flourishing association was held this year in the city of Freiburg, Baden, under the presidency of Dr. A. Claus. The proceedings opened with an informal gathering in the Concert Hall on Monday, September 17, and concluded on the following Saturday with an excursion to the romantic watering-place of Badenweiler. During the four intervening days the several Mathematical, Physical, Biological, and Medical Sections met regularly in the old University the High School, Gymnasium, Chemical Laboratory, and other local institutes. All were fairly well attended, and amongst the distinguished savants present mention may be made of Professors Stickelberger, Fischer, Hildebrand, Weismann, Maier, Drs. Hack, Nicolai, Lehmann, and Thiry. As many as 120 papers and monographs in nearly all branches of science were either read or submitted to the Association, and summaries of most of them inserted in the official journal (*Tageblatt*) of the proceedings. Of this journal four numbers altogether were issued, and their varied contents convey a tolerably accurate idea of the immense amount of work got through during the four days devoted to the special objects of the Association.

In his inaugural address the President dwelt mainly on the vast changes that had taken place in the social and political relations of Germany, and on the great progress made in all departments of human knowledge since 1838, the last year that the Association had met in the city of Freiburg. The five sections, which at that time were found sufficient for its purposes, had developed into twenty-four distinct divisions corresponding to the present conditions of science, and many of these already formed special branches of themselves, with their own independent gatherings and separate organisations. With the progress of discovery in the natural sciences this tendency to constant subdivision of labour became inevitable, and the great encyclopædic minds of former times would henceforth be replaced by specialists compelled to devote all their energies to the cultivation of one or two minor sections of particular physical or biological categories.

A discussion followed on the selection of next year's place of meeting, which was ultimately decided in favour of Magdeburg.

In the Chemical Section, Dr. Frank of Charlottenburg read a paper on siliceous sinter and on its application to chemical and medical purposes. This substance, composed of the remains of microscopical organisms, and entering into the composition of extremely porous siliceous masses, combines the properties of asbestos with those of lightness in the highest degree. It is hus capable of absorbing moisture to the extent of 94 per cent. of its own volume, and may be used without any risk as a disinfectant and for draining damp places.

In the Zoological Department, Dr. Gräff of Aschaffenburg described the results of his investigations of some new species of Myzostoma, completely confirming his former views regarding he relationship of the Myzostomidæ to the Tardigrade family. He explained the reproductive processes of the Myzostomæ, and he form of their cysts, and reported the discovery of these cysts n fossil crinoids. He also gave an account of the germs of *Volvox viridis* in filtered water exceptionally developed from olourless individuals. Dr. Döderlein described some fossil ponges from Japan of highly intricate structure, but all developed originally from simple Radiate types. They were related Tetractinellidæ, and more particularly with Pachastrella.

The journal for Friday, September 21, is largely occupied ith an extremely interesting monograph by Prof. Hertwig of na on "Symbiosis in the Animal Kingdom." This term mbiosis, first suggested by De Barry in connection with certain henomena of the vegetable world, is here extended to the whole ganic system. As distinguished from ordinary parasitism, it explained to mean the normal fellowship or association of dismilar organisms, which dwell together in a common abode for eir mutual welfare. In the case of parasites the connection is ogether one-sided, one of the two organisms attaching itself the other, and flourishing at its expense, as, for instance, the stletoe on the apple-tree. But in this newly revealed phenonon of symbiosis, which appears to pervade the whole bioical world, both associates are mutually beneficial, and in ne instances even indispensable to each other. They act, so say, like two partners in a well-regulated business concern, operating in the work of life, taking part in all its toils and ubles, and honourably sharing the common profits. An illustion is drawn from the familiar hermit crab, one species of ich, after taking possession of the first available empty ll, goes into partnership with a sea-anemone (*Adamsia liata*). This lovely creature, bright orange spotted with red, aches itself to the roof of the common abode in such a posi- that its mouth and prehensile apparatus are always turned ards the head of its associate. It is thus enabled to join in the expeditions of the restless hermit crab, and conveniently re in the common plunder. In return for this service the mone protects its companion from his many enemies by ns of the numerous long threads which it shoots out at the least alarm, and which are provided with millions of capsules charged with a stinging acid like that of the common nettle. So close is the compact entered into by the two partners, that both have become indispensable to each other, as appears from a series of experiments made at the Neapolitan Aquarium. If the crab be removed from his house, and this be stopped up, so as to prevent his reentering it, he will cast about for another shell, and never stop until his old associate is also transferred to their new abode. A still more remarkable illustration is drawn from the *imbauba*, or candle-nut tree, of South America, which strikes up an alliance with a species of small black ant to their mutual benefit. The whole subject of symbiosis, which naturalists are only beginning to study, is calculated to throw great light on the Darwinian theory of biological evolution. The various cases of fellowship between animals and plants of different orders, and even between members of the animal and vegetable kingdoms show how, in the perpetual struggle for existence, the individual organism avails itself of the smallest advantage to secure a place in the household of nature. It often thus acquires marvellous habits of life, which it is afterwards unable to lay aside, and in consequence of which it becomes gradually modified in its bodily form and organisation. Thus *abyssus abyssum invocat*, one change superinduces another, altered conditions require fresh combinations, and the organic world resolves itself into an everlasting ebb and flow of life, in which the individual counts for nothing, the species—itself transitory—for but little, and the sum of existence alone is considered in the self-adjusting scheme of the universe. Symbiosis thus leads at once to a broader and more searching study of various branches of human knowledge. To prosecute the subject successfully vegetable and animal organisms must be examined, normal and morbid conditions attended to, anatomical and physiological questions investigated. For this boundless theme belongs to a border land, in which zoology, botany, anatomy, physiology, and pathology meet as on common ground.

In the Physical Section the subject of the pyroelectricity of crystals was discussed by Prof. A. Kundt of Strasburg, who explained his recently-published method for the observation and investigation of this phenomenon.

In the Mineralogical Department papers were submitted by Dr. Petzholdt of Freiburg, on the formation of coal; by Dr. Dölter of Graz, on his attempts to produce artificial gems, in which he pointed out that the mineralogical composition does not depend directly on the chemical alone; by Dr. Kloos of Karlsruhe, on the change of labrador to an albite and a zeolitic mineral. Dr. Fischer of Freiburg dealt with the question of the natural presence of nephrite, jade, and chloromelanite in various parts of the Old and New Worlds, and the great importance of these minerals in connection with prehistoric remains and early migrations. Special reference was made to the work recently published by Dr. A. B. Meyer, of Dresden, "On Jade and Nephrite Objects," and in the discussion that ensued none of the members present subscribed to the views advocated in that work.

In a paper "On the Higher Cryptogams" Prof. Michaelis bases an objection to Darwinism as a scientific hypothesis on the grounds first that the accepted theory of the fertilising process, especially in the case of the heterospores, rhizocarps, and dichotoms, rests on pure analogy, without any actual demonstration, and secondly, that in the mosses the sexual origin of the sporogonium from the mother plant shows a fresh formation of a totally distinct organism out of that previously existing. Nature thus yields an unanswerable argument against the Darwinian assumption, inasmuch as here the second individual is dependent, and under no circumstances capable of a separate existence.

Prof. Nüsslin of Karlsruhe described a new protozoon from Lake Herrenwies, Baden, the *Zonomyxa violacea*, holding a middle place between the Pelomyxa and Amphizonella of Greeff.

In the Geographical and Ethnological Sections, which were on the whole rather poorly represented, Dr. Passevant-Basel gave an account of his residence in the Cameroons, West Coast of Africa, during the months of February to June, 1883. A paper was read by the same naturalist on the African races, with special reference to the unity or diversity of the negro type. The author agrees with those anthropologists who subdivide the Negroes into several stock races, basing his conclusions on a comparative study of the hand and skull.

Prof. Doelter, of Graz, discussed the hypothesis of a vanished Atlantis, and the former possible connection of Africa and

America. From a careful study of the geological conformation of the north-west coast of Africa, of the Cape Verde, Canary, and Azore Archipelagos, he considers that a union of the two continents in remote epochs is scarcely conceivable. On the other hand, the former existence of a large island, comprising the Canaries, Azores, and Cape Verde group, may be regarded as not improbable. But whether this island was at any time itself connected with the African mainland is a question which cannot be decided without further investigation of the local conditions.

LOCAL SCIENCE SOCIETIES AND THE MINOR PREHISTORIC REMAINS OF BRITAIN[1]

IN the annual address which I had the pleasure of delivering to the Essex Field Club at the beginning of this year I ventured to put forward a suggestion which I will take the present opportunity of enlarging upon in the presence of this gathering of the representatives of so many of the local societies of this country.

Of the various branches of natural science cultivated by our respective societies perhaps no subject possesses so widespread an interest as the early history of man. It is only in recent times that materials have been gathered with anything like scientific method from the fragmentary records of the past. By the methods of modern research these materials have been coordinated into that imperfect sketch of the physical characters and mode of life of the early inhabitants of this and other countries which constitutes our present knowledge of prehistoric archæology. But vast as have been the strides in this department of knowledge within the last quarter-century, it is certain that even now we are only on the threshold of a dim region into which advance is becoming more and more difficult with the increasing scantiness of the evidence the further we penetrate backwards into the history of our race. The labours of cave-hunters and searchers into our ancient river gravels—the excavators of our earthworks and tumuli have garnered a rich harvest of facts upon which is based the existing knowledge of ancient man. The old method of solving problems in prehistoric archæology by attaching a tradition to any ancient monument of which the history was unknown has been weighed in the balance and found wanting. The erudite verbiage of the old-school antiquarian has been displaced by the shovel and pick of the modern investigator.

While the spirit of scientific inquiry is thus gradually enabling us to reconstruct some few chapters of the past history of man from such remains as have been preserved to us, the extreme importance of the relics themselves is as a natural consequence becoming more and more recognised. It must have been with the greatest satisfaction that anthropologists heard that the ancient monuments of this country, thanks to the foresight of Sir John Lubbock, were to receive Government protection. For years past the destruction of the most venerable relics has been going on, partly through local ignorance of their value, partly through wilfulness, and partly through the unavoidable clearance of ground for building and agricultural purposes. But although the larger and better-known remains are now secured from demolition, there are numerous smaller and less-known relics scattered over the country, which in the course of time are doomed to destruction by the advancing tide of civilisation. As may be seen on reference to good topographical works, the irreparable losses which anthropological science has already incurred in this way are enormous. The most deplorable feature in these cases of destruction is that they have occurred without adequate scientific supervision, and any evidence that might have been gathered by competent watchers has been for ever lost.

The systematic exploration of earthworks, barrows, tumuli, &c., by the method of excavation is necessarily expensive work, and it is to me a matter of some surprise that the munificent example set by men like General Pitt-Rivers and Canon Greenwell has not been more widely followed by those who, with the knowledge of this difficulty, have it within their means to promote this branch of research. As in the case of one of the societies which I have the honour of representing (the Essex Field Club), which at the instigation of General Pitt-Rivers undertook the investigation of the ancient earthworks in Epping Forest, good work can sometimes be done by a local society by raising a fund for the purpose of exploring such remains in its own district, and this leads me to the immediate object of the present paper.

In attempting to draw up any suggestions for the guidance of local societies, the great difficulty appears to be the impossibility of finding any subjects for research of a sufficiently general scope to be open to all societies. The subjects already proposed by the committee appointed last year by the conference of delegates are, as you are aware: (1) underground waters, (2) erratic blocks, (3) underground temperature, (4) rainfall, (5) periodical natural phenomena, (6) injurious insects. To these I am now about to suggest the addition of another subject, viz. (7) prehistoric remains. Here, as it seems to me, there is a useful field for cooperation among the societies of all counties. Thanks to the increasing interest in scientific matters now making itself felt throughout the country, there is perhaps no corner of Britain which does not or could not be made to fall into the province of some local society or field club. In view of the imminent destruction of many of the minor remains on the one hand, and the scheduling of the larger remains for State protection on the other hand, I believe that occupation of the greatest scientific importance exists for all local societies.

The time has perhaps not yet arrived for laying down any rigid system for dealing with the proposed subject, and I therefore think it advisable at present to confine myself to a few general observations respecting the nature of the work which it is desirable that local societies should take in hand. It must be understood that these remarks are limited to prehistoric archæology, as the remains belonging to the historical period are generally dealt with by archæological societies, and do not come within the range of science subjects admitted by the British Association.

Assuming then that all societies have prehistoric remains of some kind within their districts, the first and most essential thing to be done is to draw up catalogues of these relics, giving their position, external form and structure, and bibliographical references. If the societies of each county would undertake this task, arranging matters so that no relic, however apparently insignificant, escaped their vigilance, we should thus in time come to possess a complete catalogue of all the ancient remains of Britain, and at the same time we should gradually get together a most valuable collection of literary references. The bibliography is essential, because so many of our ancient remains have from time to time been investigated and the results buried in some obscure archæological paper, the disinterment of which is in itself a piece of antiquarian research. A catalogue such as the one now proposed would thus serve many useful purposes. We should have an index-guide indicating precisely where prehistoric remains exist at the present time, and further whether they had ever been systematically explored, and if so with what results. At the same time, attention would be directed to many relics which the local society and the Government inspector might deem worthy of being scheduled for State protection. By this means I am disposed to believe that the operation of the Ancient Monuments Bill would be considerably accelerated, and its effectiveness thereby increased.

It will be as yet premature to suggest any general form in which the proposed catalogue should be cast. Each society would no doubt at first work upon a plan of its own. But whatever form be adopted it is advisable that publicity should be given to the results in the Transactions or Proceedings of the respective societies, as the purely local interest in the work would be thus greatly enhanced, and the working up of the whole into one compendious catalogue might possibly be done later by a committee of the British Association composed partly of delegates from local corresponding societies, and partly of other eminent authorities in prehistoric archæology whose assistance and advice it would be most desirable to secure.

If the scheme now broached should be deemed worthy of consideration by your respective societies, it would be essential, in order to carry out the work effectively, to appoint from your councils and members ancient monument committees, whose function it would be to draw up the proposed catalogue, visiting the remains to be entered in all cases where possible, and exhausting the topographical literature in order to avoid including any fictitious remains. Where no literary references are to be found, and in cases where doubtful structures exist, it would be all the more advisable to enter these in the catalogue, with appropriate remarks, so that systematic explorations might be made when the opportunity presented itself for raising a fund for the purpose. Even when local histories or traditions are decided respecting the age of any earthwork or other ancient structure, but little credence can be attached to such traditions until actual investigations have been made. As far as my own experience goes, and from information derived from other sources, it would appear that local tradition is the bane of the scientific archæologist. There is, for instance, hardly any prehistoric monument in this country that has not been pronounced Roman by some antiquarian authority, an opinion which not only has often been proved by excavation to be erroneous, but which has also had the pernicious effect of checking further inquiry.

---

[1] A paper read at the Conference of Delegates from Local Societies and before the Anthropological Section of the British Association at Southport, by Raphael Meldola, F.R.A.S., &c., Delegate of the Essex Field Club and the Braintree and Bocking Natural History Society. Communicated by the Author.

In recommending to your societies the actual investigation of the minor prehistoric remains of your districts as a task well worthy of the attention of any scientific body, it is perhaps not wholly necessary to urge that any excavations attempted should be carried out with the most scrupulous care, and the materials removed restored if possible on the completion of the work, so as to avoid any permanent disfigurement. The so-called "exploration" of many ancient structures whose venerable antiquity should have rendered them sacred has often been conducted in a manner which can only be called an act of desecration. How frequently do we read in local histories such statements as the following:—"On —— Common there formerly stood a large mound of earth supposed to be a tumulus, which was opened by Mr. —— in the year ——, but nothing of any interest was found *except a few fragments of pottery and some decayed bones*"! Such passages as this, which is not a verbatim extract but simply an ideal specimen illustrating the kind of destruction that has been going on, lead to the supposition that the prevailing idea in opening a tumulus is the discovery of hidden treasure. Any other find is considered devoid of interest, and the scientific value of the structure is for ever lost by the scattering of its contents.

The ancient monuments committees of local societies, in addition to the preparation of catalogues and the conduction of explorations, would have another important function to fulfil: they might take upon themselves the duties of vigilance committees, keeping a watchful eye upon the ancient remains in their neighbourhood, and preventing as far as possible their destruction. In the case of minor remains which were not considered worth scheduling for State protection, opportunities would often occur for investigating without incurring the expense of systematic excavation. In the course of building or agricultural operations old ramparts are frequently cleared away in perfect ignorance of their value to the archæologist; or again, a new road has to be made, which in its course passes through the remains of some ancient earthwork now almost obliterated by the hand of time. In such cases the vigilance committee, having previously catalogued the remains threatened, would endeavour to come to some arrangement with the owner of the property, and obtain permission to appoint watchers for the purpose of recording the nature and position of any relics that might be found. The fact that local societies have not in past times been sufficiently alive to the important work which might thus have been done by taking advantage of any unavoidable demolition of prehistoric remains has led to the destruction of a vast amount of material which, under proper supervision, might have furnished facts of lasting importance to anthropological science. It remains with your respective societies to determine whether such ruthless waste of evidence is to be allowed in the future.

OBSERVATIONS ON HEREDITY IN CATS WITH AN ABNORMAL NUMBER OF TOES

DURING the last few years I have had occasional opportunities of studying heredity in various families of cats with an abnormal number of toes, and whose ancestors for some few generations at least, have possessed the same peculiarity. The observations have now been continued over a period long enough to render their publication a matter of interest. I first became acquainted with these cats in the winter of 1878, when staying near Haverfordwest. I made inquiries on seeing one of them for the first time, and ascertained that it had been obtained from Mr. Edward Vaughan, of Fern Hill, Haverfordwest, a relation of the friend with whom I was staying. Shortly afterwards I saw Mr. Vaughan, and had a long talk with him about the peculiarity. At the time I took notes of his experience, and he has since kindly written to give further information. He first became acquainted with two generations of tortoiseshell cats with the normal number of toes (living respectively to the ages of eleven and twenty). Then in the third generation the extra toes appeared (this cat died aged nineteen, and was also a tortoiseshell). This cat or the mother was brought from Bristol to Haverfordwest. The peculiarity was inherited by "Punch"—a cat now living, and fifteen years old last May, also a tortoiseshell—making four generations. "Punch" has six toes on each fore foot, and six on each hind foot, but two of her kittens have had seven on hind and fore feet, and all varieties between the extreme and normal form have occurred commonly. It is a very curious and interesting fact that now in her old age all her kittens have the normal number of toes. Mr. Vaughan is of opinion that the peculiarity is also dying out among "Punch's" descendants, but this is by no means my experience with the branch of the family I have observed. He also gained the impression that the female kittens were more affected with the peculiarity than the males. Mr. Vaughan also made the interesting observation that the peculiarity reappeared in the kittens of a normal female cat (a daughter of "Punch's"), although in smaller proportions.

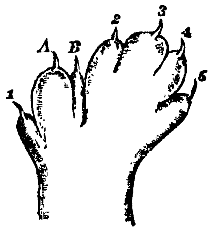


FIG. 1.—Right fore paw from above, wi·h extra toes.

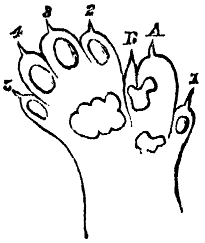

FIG. 2.—Right fore paw from below, with extra toes.

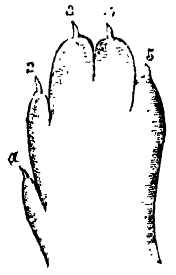

FIG. 3.—Right fore paw from above, normal.

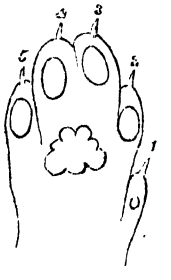

FIG. 4.—Right fore paw from below, normal.

In the spring of 1879 Mr. Vaughan very kindly sent a female tabby kitten to my home at Reading. This was a daughter of "Punch's," and it possessed six toes on each fore foot and six on each hind, thus rendering the feet very broad and giving them a most remarkable appearance. This cat, although rather wild, was very clever, being easily taught to "shake hands," and catching birds and even fish with surprising ease. When a little over a year old the first family (of four) was born, in the middle of June, 1880.

All the four kittens were tabbies, and I made the following notes of them:—(1) male: fore paws, five toes, but the insignificant innermost toe being absent, the foot appeared broad like the mother's; hind paws, five toes. (2) female: fore paws, five toes, same as (1); hind paws, six toes. (3) and (4) females: normal; five toes on fore paws, four on hind. No. (2) in this list was given to a friend, and will be again referred to. One normal female was also given away, but was soon lost without offspring; the other female was killed. There is nothing in the above list to support the view that the females are more affected than the males with the mother's peculiarity.

The next family of which I have notes was born May 13, 1881. The three kittens were tabbies as before:—(1) male: normal. (2) female: normal. (3) female: six toes on each fore and hind foot, as the mother. Here the only affected kitten is a female.

The next and last family of which I have notes was born August 26, 1881. I received notes of three kittens, but there may have been more:—(1) and (2) females: six toes on each fore and hind foot, as the mother. (3) sex not observed: six toes on all feet, as the mother.

After this I was unable to obtain notes, although many families were born, and a large proportion always possessed the peculiarity. Few people are aware of the immense difficulty in obtaining accurate notes of a simple observation such as this.

The mother was subsequently killed.

I now return to No. (2) of the first family, which was given to a friend on the condition that I received accurate notes of all families. I received *one* such account. This was of a family of four born in June, 1881:—(1) male: normal. (2) female: normal. (3) female: with five toes on the fore paws, six on the hind, same as mother. (4) female: the same as mother, but five toes on the hind feet. Here again the females possess the peculiarity. The mother was also a small, very clever cat, catching birds with the most wonderful ease. There were many families, in each of which quite half possessed the peculiarity, and many of the kittens had the same number of toes as the mother.

At last, about a year ago, a female tabby kitten appeared with *seven* toes on each fore paw, and six on each hind. This was given to me, and is now a small tabby cat, with a tendency towards tortoiseshell coloration on the back. A rough drawing of the right fore foot, as seen from above and below, is seen in Figs. 1 and 2. Drawings of a normal right fore foot are given in Figs. 3 and 4, for comparison. It is seen that the extra toes are those labelled A and B, and they confer the extraordinary breadth upon the foot. The most recently added is B, which is still partially coalesced with A, and has but one pad in common with it (Fig. 2). This last toe, B, was absent in the cat which I received from Mr. Vaughan. In the first family described, Nos. (1) and (2) possessed the largely developed extra toe, A, while the insignificant pollex (Fig. 1, 1) was absent, and thus the foot appeared extremely broad, although with only the normal number of toes. In walking the pollex does not touch the ground, but the claws A and B come down a little later than the rest of the foot, making a very distinct click when the cat is walking on floorcloth. This sound is particularly audible when the cat is coming down stairs. Comparing the pads on the underside of the foot with those of a normal animal (Figs. 2 and 4), there is seen to be an extra pad behind the additional toes, of which there is no trace in the normal foot. The left foot is similar to that drawn, except that there are traces of more complete fusion between the toes A and B in the slighter tendency towards division shown by their common pad. The right hind foot from above and below is given in Figs. 5 and 6, and a normal hind foot for comparison in Figs. 7 and 8. The correlation of the toes is more difficult here, but there is little doubt that the innermost toe (Figs. 5 and 6, 1) is the hallux, lost in the normal foot.

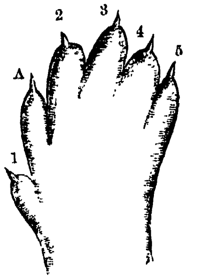

FIG. 5.—Right hind paw from above, with extra toes.

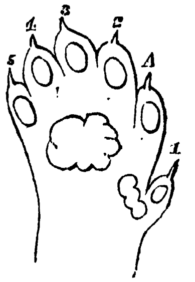

FIG. 6.—Right hind paw from below, with extra toes.

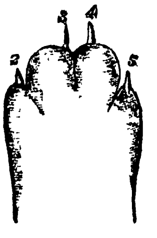

FIG. 7.—Right hind paw from above, normal.

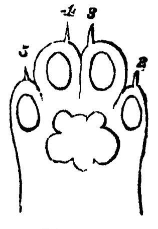

FIG. 8.—Right hind paw from below, normal.

Comparison with the fore feet renders it likely that the second extra toe is that labelled A in Figs. 5 and 6. On the underside (Fig. 6) all the toes have separate pads, and there is an additional pad behind the extra toes. This, in the left hind foot of the same animal is fused with the pad behind the other toes.

On July 10 last the cat I have just described produced a family of four tabby kittens. Strangely enough, they are all males, but they possess the mother's peculiarity to a remarkable extent.

(1) Forepaws: exactly similar to the mother's, but toes A and B are more distinct, in that they have separate pads in both feet. Hind paws: precisely the same as the mother's, even to the fact that the left hind pads are continuous and the right hind pads slightly discontinuous (as in Fig. 6). Thus this kitten exhibits on the whole an intensification of the characters.

(2) Fore paws: the pads of the toes A and B are fused as with the mother. The claw of B is broken off, but its base is seen almost springing from the outer side of the base of claw A. Both feet the same. Thus the character is rather less developed than in the mother. Hind paws: the large hind pads are continuous on both feet. All the six toes are distinct on both feet, as with the mother, but A and 2 on the left foot are united by skin, although considerable freedom of movement is possible. Here again the character is rather less than in the mother.

(3) Fore paws: pads of A and B are distinct on the right side. The claw of B is accidentally broken off. On the left side the pads are also distinct, although the toes A and B are joined by skin. Hind paws: all six toes distinct on both feet; the large hind pads continuous on both. Thus this kitten is beyond the mother in the separation of the pads of A and B on the fore paws. A and B were more distinct on the right side, where also in the mother the pad showed a greater tendency towards division.

(4) Fore paws: the greater tendency towards separation on the right side was very strongly marked here, inasmuch as the toe B is entirely absent on the left side, and the pad of A simple. On the right B is present, and its pad is joined to that of A, but a little more distinct than with the mother. Hind paws: all six toes distinct and large; hind pads continuous in both feet. Thus the character is, on the whole, less than in the mother.

This is the last observation made up to the present time, and it is a very remarkable one, in the entire absence of anything approaching the normal form, and in the fact that two of the kittens go beyond the mother, while the other two are but little behind. When the two sides differ, the difference is invariably as with the mother. At the same time the immense strength of heredity in all these cases is seen when we remember that it is practically certain that the fathers of the families have always been normal. It is quite certain with this last family, for the mother was brought as a kitten from Reading to Oxford, where there is a normal male cat living in the house with her. I have never heard of cats with the abnormal number of toes in either Reading or Oxford apart from these. Mr. Vaughan says exactly the same for his cats in South Wales. Thus we must conclude that the heredity is entirely through the females, and yet the character has gone on increasing in my branch of the stock in spite of the normal element which we should expect to be introduced and to make itself felt at each stage. I have known of the family through eight generations, and three of these have started from entirely new localities (*i.e.* Haverfordwest from Bristol, Reading from Haverfordwest, Oxford from Reading) to which they were sent as kittens. This is, of course, very important, as it has prevented the possibility of interbreeding between the abnormal cats derived from the same stock.

I hope to contribute a paper to a future number upon further observations, and upon the skeletal peculiarities that accompany the abnormality.

EDWARD B. POULTON

ON THE ELECTRICAL RESISTANCE OF THE HUMAN BODY[1]

THE writer, after premising that hitherto electricity in its application to the human body had not come up to expectations reasonable in the case of so powerful a force, and that it was evidently still in an embryonic state, mentioned some examples of the conflicting and contradictory statements made by different authorities as to its electrical resistance. These varied from 13,000 to 2875 ohms and less. He believed it was enormously overstated, and had for this reason applied himself to make some more accurate determinations. He was at once met by three obstacles:—(1) The difficulty of making good contact through the skin of a living man. (2) The limitation of the amount of current by pain, and by the fact that the rapid opening and closing of strong circuits produced a tetanic state of muscle. (3) The fact that the human body is an easy electrolyte, almost immediately furnishing currents of polarisation.

---

[1] Abstract of a paper read before the British Association at Southport, by W. H. Stone, M.A., F.R.C.P.

As regards (1), the axiomatic statement seemed to be that the poles must be infinitely large compared with the current they had to conduct. This condition he had attempted to fulfil in five different ways, two at least of which were successful: either by immersing the feet and hands in baths of brine in contact with an electrode of amalgamated lead or zinc of from fifty to a hundred square inches surface, or by soaking these extremities in brine, and then wrapping a strip of flexible lead two feet long by two inches wide about them, after the fashion of a surgical spiral bandage. The fact that the skin resistance was thus reduced to zero was proved to demonstration by an observation already recorded in NATURE (September 13, p. 463), from which it appeared that the resistance of a corpse, treated with the spiral leaden bandages from foot to foot was 1150 ohms, and with solid silver conductors thrust three inches deep into the plantar muscles was actually 50 ohms more.

Under the heading of contacts it was essential to determine definite anatomical points from which the measurements should start, and which readily admitted of linear verification. Such points existed in the prominence of the ulna at the inner side of the wrist, and the lower edge of the external malleolus at the ankle. The shortest course traversed by the current between these two points had been measured to a quarter of an inch.

There were three principal directions in which determinations had been made:—

1. From hand to hand.
2. From foot to foot.
3. From hand to foot.

No. 1 was much the same as the height of the subject, and was not liable to great variation.

No. 2 varied more, since the difference between very tall and shorter men lies chiefly in the legs.

No. 3 was perhaps the best test of the average conductivity of the body, since looped currents were sure to traverse the whole trunk, and even caused motor disturbance in the extremities not included in the circuit.

Three such observations were given, including one on a man of the exceptional height of nearly 8 feet.

As regards pain, it was noted that the E.M.F. used varied from three to ten bichromate cells of 1·8 volts each. Even the first was occasionally complained of, thus incidentally showing the goodness of the contact obtained. In morbid conditions, such as that termed myxœdema, the E.M.F. of 10 cells or 18 volts through a resistance of only 1260 ohms was easily borne, and indeed hardly felt. The third difficulty, that namely of electrolysis, was the most serious: indeed the particular metal of which the electrodes were made sank into insignificance compared with the rapid and vigorous polarisation of the moist tissues of the body itself. A rotating commutator on Wheatstone's plan, and afterwards a metronomic instrument, by which the periods of alternation could be varied, were first used, but with only partial success. A more delicate mode of discharging was found in the use of an ordinary commutator key worked like a piano with the index and middle fingers of the left hand; a double contact key, putting battery and galvanometer successively in circuit, being beneath the right index finger. The left keys being first depressed alternately, the right key produced a double deflection, while the bridge resistance was too low, which was replaced by an opposite double deflection when it was intentionally made too high. By watching the galvanometer a point was easily found where it ceased to "throw," and then three successive contacts in either direction were taken to determine resistance. In spite of all precautions, the second measurement was sometimes a little in excess of the first, owing to a polarisation-current assisting the battery. This, however, never amounted to more than about five ohms, and was easily allowed for. Between each set of observations a short-circuit key, inserted outside the bridge, was closed for at least a minute, so as to discharge patient, bath, and electrodes.

The measurement was then repeated with inverted current, and the mean taken.

One set of examples out of many was read to the meeting. Three men of very different heights were tested according to the following table:—

	Height.		Weight.		Ulna to malleolus.		Foot to foot.	Foot to hand.
	ft.	in.	st.	lb.	ft.	in.		
1. Mr. Todd	5	6	7	13	5	9¾	945	1320
2. Mr. Shackel	6	3	13	0	7	0	930	1027
3. Hungarian Giant	7	8			8	7	930	1032·5

Two of these were students at St. Thomas's Hospital; the third an Austrian now exhibiting at the Aquarium, and kindly lent to the writer for examination. All the three were singularly strong, healthy, well-proportioned men, of active athletic habits. An interesting illustration of physiological laws here incidentally cropped out, showing that, in the normal human body considered as a machine, as is the length of the osseous levers so is the sectional area of the motor muscles. This in the present instance results in an almost complete identity of the electrical resistance, increased length being very fairly balanced by increased sectional area in the conductor. A good test of morbid leanness or fatness might probably be founded on this identity.

A few words only were given to the variations of human resistance in disease and with alteration of temperature. The latter have already appeared in the columns of NATURE (on June 14 and September 13).

As regards the former, six cases of hemiplegia were cited: three on the right and three on the left side of the body, in all of which the paralysed was found less resistant than the healthy side, in amounts varying from 120 to 730 ohms. The only case which differed from this rule was that of a worker in copper, from whose secretions three milligrammes of metallic copper had been extracted, where the cupreous impregnation obviously modified the general resistance of the body, as the writer had found it to do in the case of lead and mercury also.

A confirmation of the view already expressed by the writer of the paper, that the human body follows the law of solid rather than that of fluid conductors under changes of temperature, had occurred in the instance first quoted (June 14, p. 151), where the occurrence of dropsical effusion in the lower extremities permanently reduced the resistance from the values originally given, the lowest of which was 2300, to 750 ohms.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

TEN lectures on the diseases of field and garden crops will be delivered by Mr. Worthington G. Smith, F.L.S., before the Institute of Agriculture, British Museum, South Kensington, during the week November 12-17. The lectures will be illustrated with actual examples, and new drawings of all the diseases from nature, uniformly enlarged to 1000 and 5000 diameters.

UNIVERSITY COLLEGE, ABERYSWYTH.—Mr. J. Brill, B.A., St. John's College, Cambridge, has been appointed lecturer to assist the Professor of Mathematics at this college. Mr. Brill was fourth wrangler in January 1882, and, we understand, had the honour of being one of the selected candidates for the Professorship of Mathematics at the University College, Cardiff.

SCIENTIFIC SERIALS

Revue d'Anthropologie (deuxième et troisième fascicules), Paris, 1883.—In the earlier of these two numbers M. Topinard continues the "Elementary Description of the Cerebral Convolutions in Man, in accordance with the Schematic Brain designed by Paul Broca." This is the second of the series of explanatory instructions begun in the January number. It ends with a description of the occipital fissures, peculiar to man, the simiæ, and lemurs, which Broca termed "scissure occipitale interne" and "scissure occipitale externe." In the simiæ the former of these is generally perpendicular, while in man it is often oblique in direction and irregular in position, rendering its determination difficult.—Under the title "*Transformisme*," a term used by French anthropologists for *Darwinism*, M. Mathias Duval gives the substance of his introductory lecture at the Anthropological School at Paris at the opening of the session of 1881-82. The lecturer, after giving a general idea of "transformism," passes in review the services rendered to the modern science of evolution by Darwin's precursors, Lamarck and Etienne Geoffroy Saint-Hilaire. Next he considers the researches and theories of Darwin, the objections which have been made to some of his deductions, and the evidence and facts which can be brought to support his theory, with reference specially to the importance of the labours of Haeckel and other contemporary naturalists, who have contributed to the development of the Darwinian doctrines, while he lastly draws attention to the various applications of these views beyond the sphere of natural science, strictly so called.—In a paper on the Iroquois Indians Dr. Ten Kate has embodied the most important results of his observations on the physical and social condition of the pure redskins and half-breeds whom he has lately visited in the Indian reservation lands to the west of New York State. He found very few among them of pure Indian descent, but some exhibited a certain degree of prognathism, recalling the same characteristic as seen among the Malayan Liplaps. The average height of the men is 1·75 m., with a greater corresponding length of limb than is usual in whites or mulattoes. They are dolichocephalic. The colour of the eyes is reddish-brown, unlike that of any other race, while the complexion of the children is sometimes as light as that of an Italian. The half-breeds only have beards. Their principal illnesses are of a scrofulous character. The Iroquois dialects, which are gradually dying out, have not hitherto been reduced to writing, owing to the numerous anomalous guttural sounds which belong to them.—M. Bérenger-Féraud contributes an interesting paper on marriage among the negroes of Senagambia. As elsewhere among Africans, the parental tie is slight, divorce is common, women are virtual slaves, and marriages are attended with elaborate ceremonials simply as pretexts for amusements and intemperance.—M. Mondière in a review of the different races of Indo-China, supplies us with many interesting details in regard to the ethnological and anthropometrical characteristics of the Tonquins, Cambodians, and Laos, as well as of the less unfamiliar populations of Siam and Burmah.—In the third number of this year's *Revue*, we have the concluding part of Broca's description of the cerebral convolutions and fissures, which deals specially with the frontal lobes.—M. M. Duval continues his lectures on "*Transformisme*," carrying down his analysis of the most important works on the Darwinian theory of evolution to the sociological and psychological views of Herbert Spencer, and the biological researches of Huxley.—Investigations into the nature of several supernumerary muscles in the antero-internal scapulary region, by Dr. L. Testut. After Cruvilhier, who first drew attention to some of these muscles, Knott and Macalister in Ireland, and Gruber in Germany, among others, have pointed out the not infrequent occurrence of these anomalous structures in man, while in the elephant and bear, and in some of the lower quadrumana, a supernumary caraco humeral and brachial are almost always present.—The so-called "*Maye*," or May Queen of Provence, is described by Dr. Bérenger-Féraud, who traces back the festival, by which the return of the month of May is celebrated in Southern France to the ancient cult of Maia, the mother of Mercury, among the founders and Greek colonists of Marseilles. In modern times the worship of the Pagan Maia has been transferred to the Virgin Mary, in whose name alms are solicited for the little girl-child, who, veiled, and nearly buried in flowers, is supposed to represent the much venerated "Notre Dame du Mai" of Provence. These Provençal May festivals are thus closely allied to the so-called "floral games," which still survive in Cornwall, and repeat on each 8th day of May some part of the ancient Roman worship of the goddess Flora.—M. Deniker passes in review the results of the travels of M. Miklouho-Maclay on the east coasts of New Guinea, and summarises the information derived from his careful study of the Papuan races of the island, giving at the same time a number of important anthropometric measurements, together with numerous interesting ethnological and social data.

Zeitschrift für wissenschaftliche Zoologie, Band xxxviii. Heft 3, July, 1883, contains: On the embryology of *Planaria polychroa*, by Dr. E. Metschnikoff (plates 15 to 17).—On the Cœlenterata of the Southern Ocean, part 3. On the Nematophores of Plumularidæ, and on urticating cells in the mesoderm (Schirmgallerte) of *Crambessa mosaika*, by Dr. R. von Lendenfeld (plate 18).—On Karyokinesis in some Protozoa, by Dr. A. Gruber (plate 19) (*Actinosphærium eichhornii* and *Amœba princeps*).—Contributions to a knowledge of the development of the Gastropods, by Dr. F. Blochmann (plates 20, 21).—On the glands of the mantle-edge in Aplysia and kindred forms, by Dr. F. Blochmann (plate 22).—Contributions to a knowledge of the Medusæ, by Dr. Otto Hamann (plate 23).—On the cerebrum of birds, by Dr. A. Bumm (plates 24, 25).—On *Girardinus caudimaculatus*, by Dr. Hermann von Ihering (plate 26). An interesting study of this little limnophagus Cyprinoid found in Rio Grande do Sul.—Contribution to technical histology, by Prof. H. Fol.

Heft 4, August, 1883, contains: On the Cœlenterata of the Southern Ocean, part 4. On *Eucopella campanularia*, a new genus belonging to the Campanularidæ, by Dr. R. von Lendenfeld (plates 27 to 32). This memoir consists of a very elaborate and detailed description of both the hydrosome, gonophore, and ova of this new species.—On the eggshell (*Eihaut*) of *Python bivittatus*, with remarks on some other reptile eggs, and on the genesis of their outer layers, by W. von Nathusius-Königsborn (plates 33, 34).—Researches on some new Medusæ from the Red Sea, by Dr. C. Keller (plates 35 to 37).—On the manner of propagation in *Proteus anguineus*, by Marie von Chauvin (plate 38).

Archives Italiennes de Biologie, tome iii. fasc. ii. May 20, 1883, contains:—On medical instruction in Italy, by Prof. J. Bizzozero.—On the sanitation of the Roman Campagna, by C. Tommasi-Crudeli.—On the therapeutic effect of prolonged tepid baths in pneumonia and typhoid fever, by C. Bozzolo.—On the structure and affinities of the olfactory lobes in the higher Arthropods and the vertebrata, and on a contribution to the histogenesis of the internal molecular layer of the retina, by G. Bellonci.—On organic particles in the air of high regions, by P. Giacosa.—On the action of cotoïne and paracotoïne, by P. Albertoni.—On lung epithelium and its transformations in disease of that organ, by C. Bozzolo and B. Graziadei.—On the comparative anatomy of the skull of the Terramare pig, by Prof. P. Strobel.—On ptomaines, by J. Guareschi and A. Mosso.

Fasc. iii. July 31, 1883, contains:—On the partial regeneration of the liver, by G. Tizzoni and V. Colucci.—On the presence of cystoliths in some Cucurbitaceæ, by O. Penzig (plate).—On the histology of the nervous centres, by C. Golgi (4 plates).—On the action of iodoform in saccharine diabetes, by C. Bozzolo.—On the normal structure and on alteration caused by experiment in the pacinian corpuscles of birds, by Josephine Cattani.—On negro anatomy, by Prof. C. Giacomini: (1) on the cartilage of the semi-lunar fold in the eye; (2) Graafian follicles.—On the development in Salpa, by Prof. F. Todaro.—On some experimental researches as to a new automatic centre in the bulbo-spinal tract, by Dr. J. Fano.—Anthropometric studies of criminals, by Prof. H. Ferri.—On the anatomical merits of Jerome Fabrizi d'Acquapedente, by Prof. G. Romiti.—On the secretion of bile, by Dr. B. Baldi.—On inoculation of leprosy, by R. Campana.

Proceedings of the Isis Natural History Society, Dresden, January to June, 1883.—Obituary notice of Karl Ch. G. Nagel, by H. Engelhardt.—Perceptive faculty of insects and other lower animals, by Prof. B. Vetter.—Fauna of the Suez Canal, by Dr. C. Keller. Up to the present time eleven Mediterranean species have penetrated for the most part as far as Suez, while the Red Sea yields twenty-five species, which, however, have as a rule scarcely yet reached half way towards the northern entrance.—On a case of albinism observed in the Heidelbeer district, by H. Engelhardt.—A comparative study of the flora of the Erzgebirge and Riesengebirge, by Dr. R. Kell.—On the theory of shifting continental and insular climates, with special reference to the vegetable relations of Norway, by Cl. König.—On the so-called "compass plants," by E. Stahl.—On the exploration of the flora of Lapland made by Linné in 1732, by Dr. O. Drude.—On the presence of Anodonta and Planorbis in the Tertiary lignite beds of Schellenken, by Dr. Deichmüller.—On the source of the nephrite found in North Germany, by H. Credner.—On the river valley formations in the Western Erzgebirge, by J. Jacobi.—On the geological formations of Mittweida, with special reference to its flora, by R. Beck.—On a fossil bird from the Bohemian chalk beds, by H. B. Geinitz.—On the presence of copper in the syenite of the Plauenscher Grund, Saxony, by F. Zschau.—On the limits of the Dyas and Trias systems, by A. Dittmarsch.—On the relation of the protoarseniate of iron to the iron oxide in the magnetic iron ore of Berggiesshübel, by H. Vater.—On G. Laube's "Traces of Man in the Quaternary Formations of the Prague District," by Dr. Deichmüller.—On the bronze and iron objects found in the clay beds of the Wendish Circle, Lievland, by A. Engelmann.—On H. Schliemann's "Ilios, City and Land of the Trojans," by H. B. Geinitz.—On a prehistoric find on the Hradischt near Stradonitz, by W. Osborne.—On an ancient burial place at Kunzowo, by F. Raspe.—Find of stone axes at Dippoldiswald, by H. Wiechel.—On some new views respecting the mutual relations of biological and chemical research, by D. W. Hentschel.—On Prof. Lindemann's proof that π is not an algebraic quantity, by Dr. Harnack.—On the preparation and application of perspective models in relief, by Dr. Burmester.—*On the general theory of the so-called P.E.* system, by Prof. Voss.—On the supposed coprolite deposits of Helmstadt, Büddenstedt, and Schleweke, near Harzburg, by Dr. H. B. Geinitz.—Memoir on the diluvial glaciers of North Europe, with special reference to Saxony, by Dr. H. B. Geinitz.—A Gaulish double grave at La George-Maillet, Marne, by D. von Biedermann.—Monograph on the climate of the Glacial epoch, by Heinrich Vater.—The diamond fields of the Cape, by Thaddeus Schrader.

SOCIETIES AND ACADEMIES

LONDON

Mineralogical Society, October 22.—Anniversary Meeting.—W. H. Hudleston, F.G.S., president, in the chair.—The following were elected officers and Council for the coming session:—President, Rev. Prof. Bonney, F.R.S. Vice-Presidents: Rev. S. Haughton, M.D., F.R.S.; W. H. Hudlestone, M.A., F.G.S. Council: G. S. Boulger, F.G.S.; C. O. Trechmann, Ph.D., F.G.S.; Mr. J. Stuart Thomson, Rev. Prof. Wiltshire, F.G.S. (in place of Messrs. Church, Danby, Merry, and Walker). Treasurer, R. P. Greg, F.G.S. General Secretary, R. H. Scott, M.A., F.R.S. Foreign Secretary, C. Le Neve Foster, D.Sc., F.G.S. The Secretary read the Report, which was adopted. The outgoing President delivered a short address, and the chair was taken by Prof. Bonney, when the following papers were read:—J. Stuart Thomson, on crystals of calamine from Wanlockhead.—A. S. Woodward, on the occurrence of Evansite in East Cheshire.—Mr. S. Henson exhibited a magnificent group of crystals of stibnite from Japan.—A vote of thanks to the outgoing president, Mr. Hudleston, concluded the proceedings.

SYDNEY

Royal Society of New South Wales, September 5.—C. Moore, F.L.S., vice-president, in the chair.—Five new members were elected, and eighty-nine donations received. The following papers were read:—Notes on the genus Macrozamia, with descriptions of some new species, by C. Moore, F.L.S.—A list of double stars, by H. C. Russell, B.A., F.R.A.S.—Some facts connected with irrigation, by H. C. Russell, B.A., F.M.S., &c.—On models for showing crystallographic axes, by Prof. Liversidge, F.R.S.—On the discolouration of white bricks made from certain clays in the neighbourhood of Sydney, by E. H. Rennie, M.A., D.Sc.—Mr. J. K. Hume exhibited a collection of Carboniferous fossils from Cataract Creek near Mount Wellington, Hobart, Tasmania, which were described by C. S. Wilkinson, F.G.S.—Prof. Liversidge exhibited a fossil specimen of an extinct Chelonian reptile (*Notochelys costata*, Owen) from the Flinders River, Queensland, being the first Chelonian found in Australia.

PARIS

Academy of Sciences, October 22.—M. Blanchard, president, in the chair.—River navigation; endless chain towing, by M. Dupuy de Lome. The author describes the recent experiment made on the Rhone of a new system of towage, which appears satisfactorily to solve the problem of the economic transport of goods on this most difficult of navigable rivers, and, *a fortiori*, on all streams with a moderate current. The success of the experiments is due to the employment of two endless lateral chains, worked with independent machinery by a single hand, and serving at the same time to steer the vessel.—Note on a formula of Hansen applicable to the celestial mechanism (continued), by M. F. Tisserand.—Disinfection of ornamental plants intended for exportation, by M. Laugier. The successful experiments made in concert with Dr. Kœnig of Asti at the Agronomic Station of Nice in December, 1882, were renewed during the month of September last with most satisfactory results.—Note on some arithmetical theorems, by M. Stieltjes.—On surfaces whose curve is constant, by M. G. Darboux.—On the law regulating the distribution of tension in an elastic plate of arbitrary primitive form encircling a cylinder of any right section, in cases where the friction is uniform, by M. H. Léauté.—On the movement of a rolling weight along an elastic horizontal rod fixed at both ends in cases where the mass of the rod is much smaller than that of the weight, by M. J. Boussinesq. A wider application is here shown of the problem of rolling masses solved by Willis and Stokes, as described in the paper inserted by Stokes in the *Cambridge Phil. Trans.*, vol. viii. 1849.—Observations on a reply of M. Faye touching diverse phenomena of solar spectroscopy (*Comptes Rendus*, October 8, p. 779), by M. L. Thollon.—*On the inductive force due to the variation of* intensity in the electric current of a flat spiral multiplication, and on the comparison of this force with that exercised at great distances by a spherical solenoid or a solenoidal fictitious sun, by M. Quet.—Note on the determination of the equivalents of copper and zinc by means of their sulphates, by M. H. Baubigny.—On the transformation of hydrocarburets into corresponding aldehydes by means of chlorochromic acid, by M. A. Étard.—Note on the state of the sensitive nerves during the excitement produced by strychnine, by M. Couty.—On two cases of peripheric nervo tabes (ataxy of the lower members, combined with absolute integrity of the posterior roots, of the spinal ganglia and spinal marrow), by M. J. Dejerine.—On the secreting epithelium of the kidney of Batrachians (triton and axolotl), by M. J. Bouillot.—On the extent and age of the dioritic formations of Corsica, by M. Dieulafait. Instead of occupying a deep continuous vertical range, as hitherto supposed, the author shows that the Corsican diorites belong to three distinct systems—granites at San Luccia di Tollano and Ajaccio, ophiolithic or serpentine rocks of the Triassic and Permian formations at Bastia and elsewhere. With these last are exclusively associated the numerous sulphuretted metalliferous ores occurring in the island.—A discussion of the causes to which is due the movement of glaciers, by Mr. Walter R. Browne. This movement is here attributed rather to atmospheric causes (pressure and temperature) than to gravitation.—Observations on an earthquake felt at Ghadames (Algeria) towards the end of last August, by M. Duveyrier.

ZOOLOGY OF THE NORTH ATLANTIC EXPEDITION

The Norwegian North Atlantic Expedition, 1876-1878. Zoology: *Holothurioidea*. By D. C. Danielssen and Johan Koren. With Thirteen Plates and One Map. *Annelida*. By G. Armauer Hansen. With Seven Plates and One Map. (Christiania: Printed by Grondahl and Son, 1882.)

THESE two volumes comprise Nos. VI. and VII. of the results of the Norwegian North Atlantic Expedition. The first, which deals with the Holothurians, contains an interesting account of several new genera (5) and species (6). Of the new forms *Kolga hyalina* is perhaps the most interesting; it has been placed in the family Elpididæ, of the order Elasmopoda, instituted by Dr. Théel for some of the Holothurians collected during the *Challenger* Expedition. Kolga is a small Holothurian (the largest specimen dredged measuring 50mm. in length, 15-20mm. in height, and 12-15mm. in width) with the oral disk facing the ventral, and the anal orifice the dorsal, surface, and having a dorsal collar bearing sucker-like contractile papillæ at the anterior extremity. These papillæ, unlike ordinary pedicels, were found to communicate with the perivisceral cavity by means of spaces formed within the collar.

After referring to lateral and terminal conical suckers, the translucency of the skin, and cutaneous cellular glands, the authors give a careful description of the water vascular system, dwelling especially on the sand canal, which is especially interesting, for instead of hanging free in the perivisceral cavity, as in the ordinary Holothurian, it opens directly to the exterior in front of the collar. The larval condition thus persists, the circular vessel retaining its communication with the exterior through a simple membranous tube. In two other Holothurians from this Expedition, constituting the new genera of Trochostoma and Irpa, the sand canal has the outer end attached to the skin but not in communication with the exterior, and in each case there is a madreporic plate developed on the canal within the point of attachment. In Elpidia there is a similar arrangement, but the madreporic plate is rudimentary or wanting, hence the authors think that Elpidia approximates more closely than Trochostoma and Irpa to the larval stage so perfectly maintained by Kolga. With respect to the blood-circulating system, Kolga differs from the general plan in which the dorsal and ventral vessels originate between the stomach and the intestine, for in Kolga they open from a ring encircling the œsophagus, and as this ring has thicker and more muscular walls than the vessels proceeding from it, it is suggested that it may function as a heart.

Of the five nerve trunks which emanate from the oral nerve ring, the two dorsal furnish an offshoot to each of a pair of large vesicles containing otoliths, and the two lateral ventral cords send branches to numerous successive auditory vesicles. Each vesicle contains from 20 to 130 otoliths. Kolga, which is diœcious and in which there is no respiratory tree, may thus be considered to be a very primitive member of the Holothurian group, near which comes Elpidia, the authors disagreeing in this respect with Dr. Théel, who, taking into consideration the bilateral form of Elpidia, gave it a high place amongst Holothurians.

Prof. Steenstrup's and Dr. Lütken's account of *Myriotrochus Rinkii*, St., has been supplemented in the above report from numerous specimens found at Spitzbergen; and *Myriotrochus brevis*, Huxley, is considered to be identical with *Oligotrochus vitreus*, described by Sars in 1865.

In describing the new genus Trochostoma (instituted for *Molpadia boreale*, Sars, *Molpadia oolitica*, Pourtales, *Haplodactyla arcticum*, and a new form, *T. Thomsonii*) the authors discuss at considerable length the function of the respiratory trees, and conclude that they are in all probability secretory organs belonging to the intestines. After dealing with another new genus (Ankyroderma) this very valuable and interesting memoir concludes with a list of the Holothurians collected by the Expedition, and a table showing the depth, temperature, bottom, &c., where each was procured.

The descriptive text is illustrated by thirteen excellent lithographed plates, and a map showing the position of the zoological stations where the various specimens were obtained.

In the memoir on the Annelids collected by the Expedition, Hansen commences by entering a protest against the number of genera instituted in this class by Malmgren, and he especially considers that the distinction on which Malmgren lays so much stress, viz. the difference between the bristles of different members of the class, is not in reality present. The scales, on the other hand, are considered by the author to be much more distinctive specific features, and from the character of the scales accordingly he opposes the wholesale heaping together by Mobius, and after him by Tauber, of proposed genera and species into a single specific group. Of a large number of Annelids procured a description is given only of new species—about 28—and of a few others which are little known. The description of these forms is almost limited to their external characters, especially to the form and structure of the scales.

The Annelids collected are divided into two groups, first, those found in the warm, and next, those from the cold, area. The list containing those from the warm area gives the depth, temperature, &c., at the various stations but in addition a useful column is added containing their geographical distribution as far as known. A further list appears of the Annelids collected in the cold area arranged under their respective families, from which it appears that most of them are represented in the frigid area, and most of the species occurring there are also found in the fjords and temperate ocean tracts. The author states that there are few indications that the deep bottom-current off the coast of Norway in which the temperature is below zero (C.) should be characterised by a fauna of its own. "Of one Annelid only, *Polynoe globifera*, G. O. Sars, can we infer with comparative certainty that its favourite, if not its sole, habitat is confined to the cold bottom-strata."

From a specimen of Serpula, *Protula arctica*, procured from a depth of 1163 fathoms, temperature – 1°·1 C., bottom biloculina clay, it is inferred that the Serpulidæ do not absolutely require solid matter on which to construct their shells. From a specimen of *Hydroides Norvegica* met with on a muddy bottom with the tube not, as is usually the case, twisted but straight, it is inferred that in such cases the tubes penetrate the mud like those of many other tube-forming Annelids.

In referring to colour and sense organs, the author says that an *Onuphis hyperborea* brought up from 299 and 412 fathoms, "a greater depth than that to which light and vegetable life are supposed to penetrate," was nevertheless vividly coloured and provided with eyes.

This volume also is illustrated by several plates and a map. The letterpress of both volumes is printed in English and Norwegian in parallel columns. They together form a solid contribution to our knowledge of two groups which are becoming more and more interesting to the zoologist.

A BUSHEL OF CORN

A Bushel of Corn. By A. Stephen Wilson. (Edinburgh: David Douglas, 1883.)

THIS little book is full of originality and force. It appeals it is true to a class, but a large class. The title is happy and suggestive, and is a sufficient text for every paragraph between the covers. It is true the subject is not exhausted, for much more might doubtless be said concerning "a bushel of corn."

But it is with a *bushel* of corn that Mr. Wilson deals. He introduces us to the bushel as an absolute measure of volume, traces its origin, mentions its varieties, discusses its merits, weighs it in the balances of justice, and dismisses it as inadequate, misleading, and impossible as a corn measure. The interest of the reader is at first excited with regard to the evolution of the bushel from terms of Roman *sextars*. Whether statistician, antiquary, historian, miller, or farmer, he must feel his interest awakened and kept alive. The bushel is seen altogether from a new aspect. Light beams out beneath and around it, and it becomes an object of respect and veneration. It is with regret that we find the fact gradually forcing itself upon us that this archetypal standard of volume, this absolute multiple of the typical wheat grain, this original bond of union between volume and weight in "merrie England," is after all as a gauge of value, and an indication of variations in price with regard to corn, an impostor. This is, however, the conclusion to which we are irresistibly driven, and Mr. Wilson, while he fondles and beams upon his bushel, is in reality dealing it its death wound. Never before has such a blow been levelled against the quarter as a measure of value in wheat.

Let any member of Parliament or of a constituency read this volume and he will rise convinced that the bushel is really doomed, and that the *cental* is the only alternative. Or let any one who is imbued with an idea in favour of the French metric system read it, and he will find that we have in England a much sounder system of quantifying than he imagined, and he will think twice before he gives up his English grain for the French gramme, or the English pint for the French litre.

The work naturally divides itself into two parts. First, an interesting inquiry into the historical origin of the bushel. Secondly, an attack upon the bushel as a means of quantifying corn. We propose to look at both these aspects. First, then, in the language of the author, "What is a bushel of corn?" The chief interest in the answer to this question lies in the fact that the bushel is based upon a unit—namely, an increment of wheat. The French have taken distilled water at 4° C. as the medium for connecting weight and volume. The Romans appear to have taken wheat for a similar purpose. The supposed base of the corn measures was not the money sterling of 24 grains used in weighing gold and silver, but the commercial or tron sterling of 32 grains used for heavy goods. In the book known as "*Fleta*" we are told that "in the English kingdoms the king's measure was made from the penny called the sterling, which is made round; that this sterling should weigh 32 grains of average wheat; that twenty pennies make an ounce, and that twelve ounces make a pound of twenty shillings weight and number; that the weight of eight pounds of wheat makes the measure of one gallon; that eight gallons of wheat make the bushel, eight of which constitute the common quarter." The sextar pint of the Romans held one London pound of twenty shillings or 7680 grains of wheat of the quality giving 64 lbs. to the bushel. A bushel was 64 sextars, and hence a London pound of really good wheat and a sextar pint united the ideas of weight and measure. According to this view a bushel of good wheat ought to weigh 64 lbs. and to hold 64 pints. The latter statement is true at the present day, and in certain cases the weight may be 64 lbs. also. Mr. Wilson, however, considers that the typical bushel of wheat was not considered to be 64 lbs., which is unusual, but 60 lbs. And, still further, that the ideal bushel of 60 lbs. was probably 60 lbs. *avoirdupois* and not London. In working out this very interesting point, Mr. Wilson shows that, according to "*Fleta*," a sack of wool was always considered to be of equal weight with a quarter of wheat. Now wool was quantified by tron weight, and if the assumption is correct that wheat was quantified by avoirdupois we can readily see if we can bring the two into accord. "'*Fleta*' tells us that 12½ merchants' pounds of 15 ounces made a stone of wool, and that 28 stones made a sack of wool equal in weight to a quarter of wheat." The weight of the sack of wool would therefore stand thus:—

Tron oz. = 640 grs.

15

Tron lb. = 9600 grs.

12½

Wool st. = 120,000 grs.

28

Sack of wool ... ... 3,360,000 grs. = 480 lbs. avoirdupois.

The comparison with the weight of a quarter of wheat would stand thus:—One bushel of 60 lbs. avoirdupois = 420,000 grs., and 8 bushels or 1 quarter = 3,360,000 grs. = 480 lbs. avoirdupois. The true solution of this difficulty therefore seems to be arrived at, namely, that the bushel of 2218·192 cub. in. is equal to 64 Roman sextars and to 64 English pints. It holds 8 gallons or 64 pints of wine, and 8 gallons or 64 pounds of really good wheat. It is equal in size to the old Scots or Linlithgow firlot, and holds 80 avoirdupois or Roman pounds of water.

The idea of a system of weights and measures based on a sound unit like a sextar pint of twenty shillings, invests our system with a halo of antiquarian interest derived from the standards of Imperial Rome. "I can see," says Mr. Wilson, with well-timed enthusiasm, "the spirit of the old Scots measures standing in an empty Linlithgow wheat firlot, with a wreath of golden ears around his brows, and looking ineffable scorn upon the statutes which affect to abolish his reign and his dynasty."

Those who want to know more must read the book. We next proceed to take a rapid glance at the objections to the bushel as a corn measure, or as a means of quantifying corn. These objections may be summarised as follows. First, the bushel lends itself easily to misrepresentation. It can be "shaken together, pressed down, running over." However exact as a measure of fluids it is not suitable for a compressible substance. The height from which a bushel is filled affects its amount; a blow upon its side during filling causes evident settlement, and finally we are not certain as to whether a heaped bushel or a struck bushel is always meant. Such is one class of objections. Another arises from the fact that, contrary to general opinion, Mr. Wilson holds, and we think proves, that weight per bushel is not an indication of quality. Samples may be readily "sweated," rubbed, beaten, or dressed, until the weight per bushel is not a fair indication of quality. Again, corn which has been swollen with exposure to rain does not return to its former bulk but remains permanently enlarged. Lacunæ or hollows filled with air remain, and the bushel is rendered lighter, although we cannot hold in such cases that the quality of the flour has been injured. Again, the shape of the grain has its effect in allowing some to pack closer together in the bushel while others lie looser. Lastly, in oats the proportion of kernel to husk varies immensely, and yet this is not indicated at all by weight per bushel. A very strong point is made with reference to moisture. We have generally considered, and with some truth, that the drier a sample of wheat is the heavier will it weigh in the bushel. This it appears is not to be relied upon, and in numerous experiments it was found that after moisture had been artificially driven off the "measure weight" or weight per bushel was less than before! Thus in one case "the measure weight with no moisture in the grain was nearly 4 lbs. less than at first, with 9·35 per cent. of moisture"! This is not by any means contrary to what might be expected. As long as wheat contracts in volume as it dries, so long will it increase in specific gravity. When, however, it reaches a stage at which the moisture evaporated is replaced by air occupying the spaces previously occupied with water—then will the weight per bushel suffer. Hence a very strong case is made out against the bushel and the quarter as standards for quantifying corn.

The question has a retrospective as well as a prospective interest. The bushel weighs differently every year. Thus, according to evidence laid before the Fiers Court in Aberdeenshire, the weight of a bushel of wheat was, in 1856, 57·02 lbs.; in 1857, 60·3 lbs.; in 1858, 61·32 lbs.; in 1860, 55·95 lbs.; and in 1868, 62·29 lbs. A bushel of wheat then between 1856 and 1868 was found to vary in weight by 6·34 lbs., or 50·72 lbs. per quarter of 8 bushels.

If wheat weighs 50·72 lbs. per quarter less one year than another, it will be found that as a standard of value the quarter is misleading. A quarter of 430 lbs. is 10 per cent. in weight less than one of 493 lbs. Now if in a bad year the lighter wheat is quoted at 48*s*. per quarter, while in a succeeding good year the heavier wheat is quoted at 52*s*., wheat is said to have gone up 4*s*., whereas according to weight the prices are the same in both years.

Wheat may be dearer per quarter and yet be really selling at less money per cental. Hence the calculations made by statisticians as to the fluctuations in the wheat market have up to now all been made on a false basis. It would take us to undue length if we were next to show from this little volume why the *cental* is a better means of quantifying wheat than the bushel or quarter. That it is so we have no doubt whatever, and therefore consider that the book before us has done much to inaugurate the use of the *cental* and the abolition of the quarter in our corn markets.

JOHN WRIGHTSON

OUR BOOK SHELF

Catalogue and Handbook of the Archæological Collections in the Indian Museum. Part I. Asoka and Indo-Scythian Galleries. By John Anderson. (Calcutta, 1883.)

THIS is a model of what a guidebook to a museum should be. The antiquities described by Prof. Anderson are of the highest interest, and the fullness and clearness of his description is worthy of them. The Indian Museum, though only founded in 1866, now contains a mine of wealth for the Indian archæologist. The collections of the Asiatic Society deposited in it have been enriched by the sculptures from Bharhut, the Gândhâra bas-reliefs, the Buddha Gayâ discoveries of the Archæological Survey, and the casts from the early temples of Orissa. A flood of light has been thrown on the history of ancient Buddhist art and belief, as well as upon the relations of Buddhist India with Greece and the west. The dome-shaped Stupa of Bharhut belongs to the second century B.C., and is adorned with sculptures representing scenes from the legendary life of Buddha; the ruins of Buddha Gayâ have been excavated near the site of the famous Bodhi tree under which Buddha sat, and which was visited by the Chinese pilgrim Hiouen Thsang in 637 A.D., while the rock-cut temples of Orissa carry us back to a period still earlier in the life of Buddhism than that of Bharhut. In the Indo-Scythian Gallery the most interesting remains are those from Mathura (or Matra) and Gândhâra. Here, too, the sculptures are partly Buddhist, though also partly Jain—Jainism itself being but an older form of Buddhism, if we are to believe Mr. Thomas. The chief interest attaching to them is due to the fact that many of them owe their inspiration to Græco-Roman—if not even Byzantine—art. The dress of several of the figures represented in them is also interesting as pointing to a northern climate. The same may be said of a group of figures at Sanchi, which have bandages round the legs like those still worn in Afghanistan.

In looking through this catalogue we cannot fail to be struck by the contrast between the care now taken by the Indian Government of the antiquities of the country, and the official neglect to which the ancient monuments of our own islands are exposed. To say nothing of the Archæological Survey, which has already done so much to bring to light the hidden treasures of early Indian art, no pains seem to be spared to protect the memorials of the past which are scattered over the surface of the soil. It is a pity that some little of the intelligent interest taken by the Indian Government in the historical monuments of India cannot be reflected on our rulers here. It is true that, fortunately for archæology, India is still governed by a small body of educated men, while an extended franchise implies a majority which cares nothing for science and much "for the rights of property" and the prospect of increased dividends; nevertheless even the majority is willing to follow the leaders it has chosen, and the leaders *will lose nothing if they remember that we have duties to perform towards the past as well as towards the present.*

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Green Sun

THE appearance of a bright green sun for several days in succession seems to be a phenomenon sufficiently rare to deserve notice in your columns, so I send you the following notes on the subject:—

On Sunday evening, September 9, the sun for some time before setting appeared perfectly rayless and of a bright silvery-white colour, quite different from anything that I have ever seen before. On the following morning I did not observe it particularly, but in the evening I watched it carefully from about five o'clock till sunset. At first it had the same silvery-white appearance as on the previous day, and this continued till 5.30, when it was lost behind a bank of cloud; on its partial reappearance, however, at 5.43, the part visible between the clouds was of a bright pea-green colour. On Tuesday morning it was rather cloudy, but the appearance, when seen at all, was the same as on the preceding night. In the evening, however, it was a magnificent spectacle, and attracted the notice of every one. The silvery sheen was visible early in the afternoon, and the brightness of the sun rapidly faded, till by about five o'clock one could look at it directly without any difficulty. At this time there was a distinct tinge of green in the light when received on a sheet of white paper, while shadows were very prettily tinted with the complementary pink. As the sun sank towards the horizon the green became more and more strongly marked, and by 5.30 it appeared as a bright green disk, with a sharply-defined outline. In fact the definition was so good that a large spot (about 1′ long) was a conspicuous object to the naked eye. On this occasion the sun was lost in a bank of clouds near the horizon, but on another occasion, when I was able to see it actually set, the colour got yellow rather than green close to the horizon. Similar, but less marked, were the appearances both at sunset and sunrise for several days, and before sunrise and after sunset the cloud effects were such as I have never before witnessed here. These cloud effects were chiefly remarkable for the brilliancy of the colouring and for the length of time that they were visible, being seen for nearly an hour after sunset. The moon and stars, when near the horizon, showed the same green colours as the sun.

On the 22nd the green sunrises and sunsets began again and continued for three days. I carefully examined the spectrum on every possible occasion with my zodiacal light spectroscope, as well as with a small direct-vision one. The spectrum showed clearly that aqueous vapour played a large part in the phenomena, for all the atmospheric lines usually ascribed to that substance were very strongly developed. But in addition to this there was a very marked general absorption in the red. Even an hour before sunset, and often longer, the absorption was complete as far as B, and the dark shade gradually crept up till it reached C, and at times even that line was invisible, while the absorption was clearly marked up to W.L. 621. At the blue end nothing could be seen beyond W.L. 428, and even that only with a very wide slit, but a photograph showed the lines clearly *nearly* as far into the ultra violet as on ordinary occasions. The phenomenon was visible over a large area of country, from Ceylon to Vizagapatam, and as far west as Aden. It was not, however, observed at all at the Bombay Observatory.

I am at present collecting information from various sources, and so do not care to enter into many details at present.

Most people ascribe the phenomena to the recent great eruption in Java, but there are difficulties in the way of accepting this view, which I have not yet been able to get over, and the similar appearance of a blue sun over Europe and America in 1831 seems to make this explanation unnecessary, besides it is well known that the sun appears green under certain circumstances when seen through steam or even in a mist (Lockyer). On the other hand, observations referred to in NATURE, vol. xviii. p. 155, tend to show that very fine dust might produce the observed effects.

Can any of your readers refer me to Dr. Schuster's original papers?

It may not be without interest to add that on both occasions the green appearance was preceded by abnormal electrical conditions of the atmosphere. The potential of the air was strongly negative for a number of days in succession from about 9.30 a.m. to 2.30 p.m., with a clear sky and no rain within 100 miles.

C. MICHIE SMITH

Madras, October 10

I INCLOSE a letter giving an account of the green sun, which may be of interest to your readers. My correspondent is the wife of General Tremenheere, formerly in the Indian army.

WARREN DE LA RUE

73, Portland Place, W., November 3

Spring Grove, Isleworth, November 2

IT may interest you to hear that my daughter, writing from Bellary, tells me that a gentleman who was at Ootacamund, in the Neilgherries, was on one of the higher peaks when the phenomenon of the sun took place in September, and he first distinctly saw a *green, cloud-like mist* pass across the sun, and *then one of a reddish colour*, and the sun took the colour of each of these clouds or mists. People at Ceylon were terribly alarmed at the unusual appearance of the sun.

S. S. T.

MR. GREAVES has the pleasure to forward to the Editor an extract from a letter just received from Mr. Beardmore at Madras, referring to the phenomenon of the green sun now being discussed in NATURE.

Sunhill, Clevedon, November 2

Harbour Works, Madras, October 10

WE have had the sun here for some weeks past in the mornings and evenings a most curious greenish blue colour, and generally casting a bluish beam of a most pretty tint. Mr. Pogson thinks it due to volcanic dust and sulphurous gases from the great eruption in Java. Another astronomer, Mr. H. Smith, thinks it due to a great amount of aqueous vapour.

NATHL. BERNARD BEARDMORE

The Division of the Circle

ALLOW me to point out an oversight in NATURE (vol. xxviii. p. 598), where, in explaining the divisions of a circle the following passage occurs: "In quite recent times it has been suggested that 400 parts should be taken in place of 360, but that is a suggestion which up to the present time has not been acted upon."

We probably owe our degrees either to the earlier supposed year of 360 days, or to the fact that this number has many divisors, although such divisors afford no practical advantage. When trigonometrical functions were subsequently discovered, it was found that the natural unit is not the circle, but the quadrant or right angle. Our system of numeration being decimal, it was then most convenient to divide the quadrant decimally, and the circle is thus considered as composed of 4, 40, 400, &c., parts according to the degree of exactness required. This was proposed by Briggs when preparing his logarithms, which are based on decimals, but unfortunately it was then set aside. Revived a long time after by Lagrange, it was acted upon by Laplace in his "Mécanique Celeste," being thus much more than a mere suggestion. Nowadays decimal divisions of the quadrant are the only ones used by French geodesists.

Facts are the grand supporters of argument. Will you kindly quote the following? After grumbling on the necessity of using the only circle at his disposal because it was divided decimally, a French civil engineer would afterwards employ no other: he found the decimal circle much more convenient. A special experiment had been already made in Italy, where two geodesists, carefully interchanged and inspected, had been instructed to observe and calculate in both systems the same large lot of angles. It was then found that the use of decimals gave a saving of two-sevenths of time either in observation or in calculation. This result was unknown to Sir George Airy, the ablest astronomer of our time, but he judged rightly that the conversion of all sexagesimal angles into decimal ones would materially lighten his labours, and he actually did so when calculating all the lunar observations previously made at Greenwich. This was the largest quantity of reductions ever made by one astronomer, and they were abridged by the use of decimals. The real supporter of sexagesimal divisions is routine, that sly enemy of progress.

Abbadia, November 2 ANTOINE D'ABBADIE

Christian Conrad Sprengel

It has now become a standing topic that C. C. Sprengel's treatise on the structure and fertilisation of flowers "after well nigh a century of oblivion has come to be recognised as one of the most interesting books, and his theory of the adaptation of flowers to fertilisation by insects is one that will ever be associated with his name" (NATURE, vol. xxviii. p. 513). Some writers go so far as to speak of a rediscovery of Sprengel's treatise by Darwin. But it should be acknowledged that Darwin himself says only ("Cross Fertilisation," p. 5): "His discoveries were for a long time neglected." So it seems to be true that Sprengel's and Koelreuter's works were unknown to English naturalists, though Kirby and Spence, at the end of Letter IX., published 1815, and in all subsequent editions till 1867, have given a very fair report in their masterly manner. Not only the facts, but also the importance of these discoveries, are fairly expounded.

In Germany these discoveries were well known to every naturalist during the whole century. In 1829, when a mere boy, my father began to instruct me in entomology. Many times he took Sprengel's work from the shelves in his study, and explained to me the discovery of fertilisation of plants by insects with the help of the plates in Sprengel's book. I have never forgotten the interest and the scientific enthusiasm of his exposition. I was told that we are indebted to a mere chance for this discovery. A rather dangerous irritation of Sprengel's eyes had the result that he was entirely forbidden indoor study by his physician, and was therefore obliged to spend his days in the field, where he was gradually led to the observation of plants, followed by his remarkable discoveries. Certainly between 1830 to 1840 at every university in Prussia the same facts were taught as well known facts of the highest importance, and of course known by every student. Prof. C. F. Burdach has related them in his large "Physiology," vol. i. p. 322, 1826, and given his conclusions. H. Burmeister, "Handb. d. Entomologie," vol. i. p. 303, 1832, speaks about them at some length also as well known and of the highest importance. Not only scientific publications, but merely popular works have the same statements. Pierer's "Universal Lexicon" (first edit. 1836, fourth, 1851, vol. ix. p. 942) gives a fair report. H. A. HAGEN

"Challenger" Zoological Reports

It seems to me that the reviewer of my Report on the Pelagic Hemiptera collected during the voyage of the *Challenger* (NATURE, vol. xxix. p. 3) is too hypercritical.

I refer, of course, to the paragraph in which he blames me for alluding to species under their trivial names only; and as the paragraph in question is calculated to convey a wrong impression, I should be obliged if you will kindly allow me to say a word on the subject.

It is true that some writers upon insects (or rather upon Lepidoptera only) have the very bad habit of alluding to species (of different genera) by their specific names only, and the law that forbids the practice is a good one; but it may be applied too stringently, and not altogether in the sense that its framers intended.

In my Report I had to deal with two genera, and a reader of the review who had not seen the Report itself would be justified in concluding from the words of the reviewer that I have used the specific names indiscriminately, without indicating the genus to which the species belonged. In point of fact this is not the case. The two genera are treated of separately, and where I have mentioned the trivial without the generic name, it has only been when the generic name governed the paragraph, and, when, consequently, no doubt could possibly exist as to the genus. In doing so I may have broken the *letter* of the law, but not, I think, the *spirit*; and were the work to be done over again, I think I would be inclined to follow the same course.

F. BUCHANAN WHITE

[The idea of a generic term governing a paragraph did not strike me. I had no wish to be over-critical, and I am glad to find that in all essentials Dr. Buchanan White agrees with the views expressed.—THE WRITER OF THE NOTICE.]

Barytes from Chirbury

A NUMBER of crystals of barytes have lately been acquired by Mr. Henson from Chirbury, Salop, which seem to deserve some description. The crystals vary from one to four inches in length and from one-half to two inches in breadth; they are very bright and clear, and are elongated in the direction of the brachydiagonal, resembling in appearance the barytes from Dufton; they are mostly doubly terminated, and some contain included crystals of copper pyrites. They were at once detected by Mr. T. Davies as being peculiar in form; and the reflecting goniometer revealed the existence upon them of four very well-defined forms which have not been hitherto found upon barytes, besides two more doubtful planes to which it is difficult to assign definite symbols.

The crystals are almost all a combination of the forms—

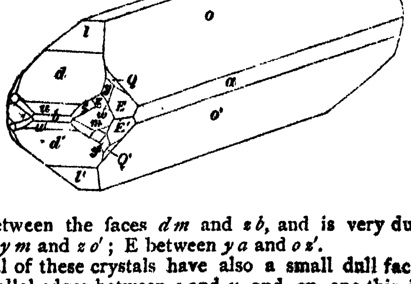
o	$\{101\}$	$\breve{P}\infty$	E	$\{412\}$	$2\breve{P}4$
d	$\{012\}$	$\frac{1}{2}\bar{P}\infty$	y	$\{212\}$	$\breve{P}2$
m	$\{110\}$	∞P	z	$\{111\}$	P
l	$\{014\}$	$\frac{1}{4}\bar{P}\infty$	ξ	$\{232\}$	$\frac{3}{2}\bar{P}\frac{3}{2}$
u	$\{011\}$	$\bar{P}\infty$	ω	$\{432\}$	$2\breve{P}\frac{4}{3}$
a	$\{100\}$	$\infty\breve{P}\infty$			
b	$\{010\}$	$\infty\bar{P}\infty$			
c	$\{001\}$	$0P$			

On some crystals were also observed—

μ (214) $\frac{1}{4}\breve{P}2$ between d and o
r (112) $\frac{1}{2}P$ between d and y
Z (034) $\frac{3}{4}\bar{P}\infty$ between u and d.

The general appearance of the crystals is shown in the annexed figure.

Of the above faces ξ, ω, E, and Z are new. ξ lies with parallel edges between the faces $d\,m$ and $z\,b$, and is very dull: ω lies between $y\,m$ and $z\,o'$; E between $y\,a$ and $o\,z'$.



Several of these crystals have also a small dull face Q lying with parallel edges between o and y, and on one this is accompanied by another small dull face Y between o and m. By oiling these faces it was possible to determine approximately their inclination to o. The measurements lead to the complicated symbols (15.1.15) for Q and (19.1.18) for Y.

The new faces, and especially E, are very characteristic of these specimens, and it is somewhat curious that faces with the simple symbols of ξ, ω, E, Z, have not hitherto been noticed among the sixty-six recorded forms of barytes.

"Anatomy for Artists"

I THINK perhaps if it were known to Dr. Marshall that his "Anatomy for Artists" is not used in cases where it otherwise would be, because of his decision to omit letters of reference in the illustrations of the bones, he might think it better to alter this in a new edition.

Dr. Marshall admits that his plan may be a strain, but perhaps he does not know how great a strain it is when students are not studying leisurely but in the limited time given in schools of art to an anatomy course. Even if he disapprove of any haste in study, he would surely be sorry to hinder rather than help those who have to be quick.

I heard recently a lecturer on anatomy refer his pupils to books inferior to Dr. Marshall's, regretting, he said, to set aside the best book they could have, but adding that, from the want of reference letters, many of the students would simply be puzzled, discouraged, and confused.

I have only Dr. Marshall's book, and although the illustrations are too good to allow of any great difficulty arising, still I have found the use of it a strain. I doubt, too, if the plan secures a "more accurate knowledge of the forms," as Dr. Marshall hopes it may. Perhaps so, after a little knowledge has been gained, but in the first struggle the student has an uncomfortable haziness as to whether he has found the right groove or prominence upon a bone, which prevents his forming a definite picture of it in his mind.

Certainly letters spoil the illustrations, but might there not be small key drawings beside the larger more finished ones.

AN ART STUDENT

Meteor

I WAS just now startled by what appeared to be a vivid flash of lightning out of a perfectly cloudless sky, a fluttering flash that lit up everything brilliantly. On turning to the south-east I was just in time to see the broad path of fire that a splendid meteor had left behind it; the meteor was falling behind some trees, and I saw it very imperfectly, but it seemed very large, and indeed *must* have been from its light. I had been looking out from time to time for shooting stars all the evening, and had seen three fine ones and four or five small ones, all in the east, and appearing to come from the neighbourhood of the Bull. The sky is covered with the lovely light that always appears with shooting stars, and which I think is sometimes called homogeneous aurora.

J. M. HAYWARD

Sidmouth, November 4

THE JAVA ERUPTION AND EARTHQUAKE WAVES

FOR the following facts the writer is indebted to the kindness of Herr Emil Metzger, formerly Director of Surveys in the Dutch Government service in Java. His original account, written before September 12, has just appeared in the *Globus*. The present paper is based upon that, but it contains several small additions and corrections which have been received directly from the author. Most of the geographical details here given are based on the Trigonometrical Survey of the coast of Java, which was carried out under Herr Metzger's immediate direction in 1868-69.

A line drawn eastwards from Flat Point (Vlakke Hoek, Tandjong Blimbing, or Rata), the south-western extremity of Sumatra, would touch the south coast of that island only in two points,—Tandjong Tikūs and Tandjong Tūwa, or Varkens Hoek. Between these promontories are the bays of Semangka and Lampong.[1] The opposite coast of Java follows generally a north-easterly direction almost to Anjer. Along this stretch it deflects, however, more than once towards the south and the east, and forms Seagull, Welcome, and Pepper Bays. Midway in the channel of the Straits, and on a straight line drawn from Tandjong Tikūs (the western side of Lampong Bay), to the western head of Pepper Bay, lies the Island of Krakatoa (called also Krakatau, Rakata), with several smaller islands near it. Sebuku and Sebisi are two islands situated between Krakatoa and the south-eastern extremity of Sumatra. About half way between Anjer and Point St. Nicholas, and only separated from the mainland by a narrow belt of water, is the Island of Merak (Pulu Merak). On the opposite mainland were the extensive quarries of Merak, which have now totally disappeared. Further, in the narrowest part of the navigable channel, lay a group of islands, of which the largest, Thwart-Way or Sunghian (Dwars in den Weg), has been rent into five pieces.[1]

From the manner in which Sebisi (the peak 2818 feet high) and Krakatoa (peak 2700 feet) rose immediately from the waves, and from the great depth of the sea around them, Junghuhn was led to conclude that Sumatra and Java, in spite of the corresponding configuration of their approximating coast-lines, and the fact that they are both volcanic, do not belong to one continuous formation. The Island of Krakatoa, considered by Junghuhn to be a continuation of the mountain system on the adjoining coast of Java, was about five miles long by about three broad; and close at its foot were the two small islands Verlaten and Long, on the west and east respectively. The Trigonometrical Survey of 1868-69 fixed the position of the cone of Krakatoa as 105° 26′ E. long, and 6° 8′ S. lat. Like most of the islands in the Sunda Straits, Krakatoa was clothed from base to summit with a luxuriant growth of forest and of tropical vegetation. When in the course of the survey the northern face of the mountain was visited in the latter year, several warm springs were found—a common enough thing, however, in these islands. Moreover, Krakatoa, as well as Sebisi, was at that time totally uninhabited, being only visited occasionally by the inhabitants of the neighbouring coasts for the sake of the products yielded by the woods.

On May 20 in the present year several shocks, accompanied by loud explosions and hollow, reverberating sounds, were observed at Batavia and Buitenzorg, each about 100 miles distant from Krakatoa. That these phenomena were not seismical was recognised at once; the magnetic needle of the magneto-meteorological observatory showed no deviation, only a trembling motion in a perpendicular direction. A few days later came the news that a volcanic eruption had taken place on the Island of Krakatoa, where nobody had once thought of looking for the seat of the phenomena. The captain of a mail steamer, however, which passed the island at about 6 p.m., has since reported that the needle on his ship was violently agitated, being spun round repeatedly.[2]

From the deck of another vessel which was passing about eight o'clock on the evening of the 22nd, a dome-shaped mass of vapour, mingled with smoke of a dark gray colour, was seen to rise from the lower part of the island. The first thing noticed was from ten to fifteen dark red "sheaves" of fire flashing up in rapid succession from the base of the column. These were followed by explosions, more or less loud, resembling discharges from artillery, so that the ship, which was sailing at no great distance, distinctly felt their influence. In the upper part of the volume of smoke appeared an uninterrupted series of flashes, differing in no respect from ordinary lightning flashes, except that they were discharged concentrically upon the column from the atmospheric clouds surrounding it. The heat emanating from the locality of the eruption was sensibly felt on the hands and face at a distance of nearly two miles away; the presence of a powerful marsh-gas was also easily detected. Several nautical miles past Krakatoa a thick shower of fine dark-gray sand continued to fall upon the ship for the space of half an hour. An apparently illimitable cloud of drifting pumice was encountered at a distance of ten miles from the island, and twenty miles farther a second cloud of pumice, which was so thick that a bucket let down into the sea was filled with it before it reached the surface of the water, while the ship, although going at the rate of 10½ knots an hour, cut through the pumice with a noise like that made by a vessel breaking way through thin ice.

---

[1] See the map of the Sunda Straits in this journal, September 6, 1883, p. 444. With this compare the map given in *Globus* (vol. xliv. No. 15, p. 233), where also fuller geographical descriptions may be found than could be given here.

[1] The earliest telegrams spoke of a volcano Sungepan, which had been split into five craters. This appears to have been a mistake; there never was a volcano of this name in this place, nor is there now. It is only an island.

[2] See the Dutch *Natuur*, September 15, 1883, p. 262.

A short time afterwards a visit was made to the scene of the eruption by a party from Batavia, and as the account of this visit contains perhaps the latest description of the condition of Krakatoa before the great convulsion of August 26, a few words from it may be perhaps not devoid of interest.

The spectacle as seen from the north of Krakatoa was one calculated to have inspired the pencil of a Doré. From the devastated island a huge, broad pillar of smoke towered upwards as high as the clouds; and while Verlaten Island gladdened the eye with its profuse display of the glories of tropical vegetation, Long Island was completely withered up,—the leafless trees, bent, twisted, and torn, but not scorched, were left standing like naked spectres, as colourless as the soil, or rather enveloped in the same neutral tint of gray, from the pumice dust, as all the rest of the island. Between these two, and only separated from each by a narrow channel, rose, somewhat in the background, the lofty cone of Krakatoa, still covered with green foliage, and without any signs of activity. But in front of the volcano all was wrecked, covered, nay, completely buried, under pumice dust, which, when the sun shone upon it, became of a yellowish-gray colour, while thick masses of condensed vapour, accompanied by incessant fulminations, boiled up from behind the bare and gently sloping dunes. These masses of vapour were for the most part snowy white, others gray, and were closely intertwined, afterwards spreading out in continually widening circles. It was as if a gigantic spectral cauliflower were with incredible rapidity evolving its successive stages of growth before the spectator's eyes. The volumes of vapour were shot out with terrific force in a strictly vertical direction; the atmospheric pressure in the middle of them must have been something fearful. And from time to time immense funnels became visible, leading outwards, and into these many of the incessantly changing ravelled wreaths of smoke were sucked. The rest maintained their original form to a height of several thousand feet; then they slowly drifted eastwards, and, spreading out into mist, discharged their ashes downwards in black streaks like the dark fringes of rain-clouds seen on the horizon. Occasionally the bellowings became louder, and a thicker and larger volume of smoke was vomited forth. Soon afterwards it was noticed that the sky in the west, which was there as bright and clear as it was dark and heavy in the opposite quarter, was being thronged with small, dark bodies,—they were pieces of pumice, of no great gravity, hovering in the air as if upheld by the power of the fiery breath that was streaming upwards. On landing, the party found that they sank up to the ankles in ashes, and accordingly it was necessary to proceed with great caution. As they slowly ascended, the ground and the air both became warmer, the evidences of destruction amongst the trees more conspicuous, and pieces of pumice lay scattered more thickly on the ground. Arrived at a height of about 200 feet above sea level, they found themselves on the edge of a "caldron" of about 700 yards in diameter, probably a former crater. Thence they saw to the north-east the seat of the recent outbreak of May 20, the maximum length of which was about 100 to 110 yards. Here, besides the volumes of vapour and smoke and pumice dust, they also observed sulphur troughs, out of which the mud boiled up in enormous bubbles, which at length burst; and sulphur springs and new but smaller columns of smoke showed themselves in other places. The noise was terrible; the sound made by the discharge of a rifle was like the snapping of a bonbon in the midst of the hilarity of a banqueting hall. Some of the party ventured to descend a little way into the crater, a few even to step tentatively upon its hot and burning floor. They brought back with them pieces of pumice and lava[1]—a kind of black glass—or a piece of sulphur as a memento of the visit. By the time they reached the steamer again darkness had come on, and the spectacle was then one of extraordinary beauty and grandeur. The great column of smoke was still tolerably visible, but the lower part had become a mass of glowing red, from which tongues of yellow flame continued to dart incessantly. At intervals a shower of fine sparks broke out from the cloud, and red-hot stones clove fiery furrows in the air, and fell back at an acute angle to the earth, where they were shattered into a thousand pieces.

That the activity of the mountain was continued during the months of June and July is certain from the report of the Comptroller of Katimbang (on the easternmost promontory of Sumatra), who observed several violent detonations. Also from other places in Sumatra, and particularly from Mexapi (100° 28′ E. long., 0° 20′ S. lat.), came tidings of volcanic movements; and similar reports arrived from Java.

Then came the outbreak of August 26, surprising, inconceivable, in its terrible effects. Although full and detailed reports are not yet to hand, as indeed from the nature of the circumstances they cannot well be expected to be, for communications are in great measure interrupted, destroyed, and rendered impossible, or those who should have made the reports have either fallen victims to the catastrophe, or have fled—who knows where?—yet sufficient intelligence has reached us to justify an estimate of the number of the victims who have perished at tens of thousands; and as for the amount and extent of the material damage done, it is so great that an approximate calculation even cannot be attempted.

The plain simple facts to which all this is due were the eruption of August 26, and particularly the ocean wave which succeeded it on the following day.[2] This destructive wave appears to have started from Krakatoa, or its neighbourhood, as a centre, to have dashed with terrific force upon the contiguous coasts of Java and Sumatra, to have proceeded down the Sunda Straits eastwards with a height that reached from 40 to 100 feet in the narrow throat of the pass opposite Anjer, and 17 feet at Batavia, and even to have extended to the western and eastern shores of America, where it was observed on the 27th and 29th respectively. Not to repeat what has been already stated in this journal (vol. xxviii. p. 443), it will be sufficient to add that a few days after the occurrence we learnt in Europe from official telegrams that Tjiringin, Anjer, and the quarries of Merak, as well as the cone of Krakatoa, had disappeared from sight. But further intelligence from Java, of August 28, states that Krakatoa has not entirely disappeared.

Although information respecting the extent of damage and destruction caused on the south coast of Sumatra is still very meagre, it appears that the two bays of Lampong and Semangka have been rendered totally unfit for navigation owing to the immense masses of floating pumice with which they are covered. In Lampong Bay, notwithstanding that it was protected by certain islands, the momentum was so great that at Telok Betong a Government steamer was carried three miles inland. Telok Betong itself, the chief town of the Royal Lampong District, is, with the exception of the resident's house, the fort, and the prison, completely destroyed.

---

[1] This deserves particular notice. Herr Metzger ascended several of the volcanoes of Java, and often stayed days and weeks together upon them and in their immediate vicinity without ever once finding what was, strictly speaking, lava.

[2] It is now stated that waves, but of no extraordinary height, were observed at 6 p.m. on August 26.

Fortunately the district as a whole was not very populous. According to the *Royal Almanac* for 1883 there was on an area of nearly 10,100 English square miles a population of 70 Europeans (excluding the military force), 128,939 natives, 255 Chinese, and 154 Arabian and other foreign races. No exact estimate of the loss amongst these has yet reached Europe; all we know is that it has been very great, and the destruction to property not less so. Except the three parallel chains of volcanic origin which stretch from north-west to south-east in the three promontories already mentioned, the country is flat and monotonous, and covered with thick woods. In these are the scattered villages and fields of the native population.

On the opposite coast of Java it is the Residency of Bantam which has borne the full brunt of the wave. We learn that at Tjiringin and Anjer it reached a height of nearly 100 feet. Accordingly all along the coast from Java's First Point to Anjer everything must have perished. And although no accurate or detailed returns of the number of lives lost in this district have yet come in, it may perhaps help us to form some conception of what it will probably amount to if we state that Bantam, on an area of about 3200 square miles, had a population of 350 Europeans, 565,438 natives, 1479 Chinese, and 21 Arabs and others. Between Java's First Point and the country to the south of Tjiringin a range of low hills, by alternately advancing and receding from the coast, formed several small bays and coves, the shores of which were more or less thickly studded with native villages and flourishing tracts of cultivated soil. But these were less frequent in the western part on account of the tigers. On the eastern margin of Pepper Bay, south of Tjiringin, the country was more flat and level, and, preserving this character, extended farther inland. But from Tjiringin to Anjer the mountains approached close to the sea. Along their base ran the chief highway to Anjer, thickly set with prosperous villages, while several others hung on the slopes. Here the full force of the great wave was expended; being broken against the rocky walls, it seems to have swept round them on the north and south and to have completely covered the lower-lying districts about Anjer and Tjiringin. South of Anjer was a bay and small valley running eastwards into the land and bordered by ranges of hills called Kramat Watu, which form the connecting link between the mountain systems to the north and south of this point. The sea is now said to wash the foot of these hills, the invasion having come from the west. It has been already stated that Tjiringin, Anjer, and Merak have disappeared; and all the ground which the inundations have not swept away is now covered with ashes. Tjiringin had six European households, while in Anjer and Merak together there were twenty-two.

Further reports, necessarily imperfect, have come in of the ruin caused by the inundations along the whole extent of the north coast of Java right away to Batavia, and even still farther. Bridges have been swept away, dams broken down, villages swamped, and the cultivated land washed bare by the floods, causing, as everywhere else where they appeared, great losses of life and still greater losses in property. In Tanara alone 700 corpses have been already found. Notwithstanding the facts that the ocean wave, when once it had emerged into the Indian Ocean southwards and into the Java Sea northwards, had more room for expansion, that the Javan coast then formed a kind of angle running back into the land, and that several small islands to the north of Batavia acted as a sort of breakwater, the great wave still possessed such strength that it drove a man-of-war ashore on one of these islands and tore away its floating deck. At Tandjong Priok the sea was observed (unfortunately the time is not given) to rise to a height of more than seven feet above the normal level, and then immediately afterwards to sink ten feet below that point, thus giving a difference of seventeen feet, while the average difference between ebb and flow is not quite three feet. The water poured in through the narrow opening (410 feet wide) between the inner and outer harbours like a waterfall, and, having filled the basins, flowed out again in the same manner.

According to the accounts received up to the present time, everything to beyond Pandeglang (south of Serang) is covered with ashes, and everything that was in the fields has perished. Very considerable damage has also been done to the lightly constructed bamboo houses by the shower of ashes, so that more than half the population (the north-east portion of the district is by far the most populous) are without means of sustenance, and, what is of far graver consequence, without fodder for their cattle. Appalled by the eruption, and dreading the famine that would soon stare them in the face, they have, it is said, taken to flight, carrying off with them what they could, and leaving their territorial possessions in the lurch. It is probable, however, that this has only been in the first moments of terror, for the native is wont to cling tenaciously to his hereditary soil. It is to be hoped that the Government Commissioner will succeed in furnishing assistance, and that speedily and in no stinted measure, to these especially unfortunate people. For years they have been visited by epidemics, and have suffered great losses from murrains amongst their cattle. Indeed, during the last year alone, the population has fallen off 10 per cent. in numbers; and what makes the case so much the worse is that the Government itself has experienced from this disaster losses in public works and in its extensive coffee plantations which may safely be reckoned in millions.

What, however, was the immediate cause of this ocean wave, whether occasioned by the rising of sixteen new islands (active volcanoes?) between Krakatoa and Sebisi, or by the falling in of the cone of the former island (or whatever be the part of it which has disappeared), or whether both causes have co-operated together, must remain more or less matter for conjecture until we have more authoritative details, based on scientific examination of the scene of the disaster.

J. T. BEALBY

Mr. Meldrum contributes to the Mauritius *Mercantile Record* fresh information on the tidal phenomenon of August 27 last, a condensed statement of which may be given here in connection with the above:—

At Cassis, during the whole day, the water was coming and going, but the movement was not taken much notice of till about 1.30 p.m. The tide on that day did not rise as usual. The water came with a swirl round the point of the sea wall, and in about a couple of minutes returned with the same speed. This took place several times. Similar phenomena occurred on the 28th, but to a much smaller extent.

At the St. Brandon Islands on August 27, Capt. Rault's vessel was anchored on the west-north-west side of Avocaire Island in 3¾ fathoms, a cable's length off shore, when at 3 p.m. the water began to rise 20 feet above the highest point attained by high water. It was then ebb tide. Quickly the water receded with a very rapid motion, leaving everything dry, showing out the shoal patches quite dry, to a very long distance from the island. Before fifteen minutes had elapsed the water rose again with the same velocity for the second time, coming up to the first mark. It was not a wave, nor a billow, nor a high sea; the water was smooth, except where there were heads of coral, and there a few wavelets only were produced. This motion of the water backwards and forwards lasted up to 7 o'clock p.m., the intervals between low water and high water being greater towards the evening; at first the intervals were about ten minutes, and towards six o'clock twenty minutes. The current was setting towards east-north-east of the compass, and the velocity was ten miles an hour. At sunset the sky in the western horizon had a peculiar smoky appearance, which extended nearly to the zenith in an east-south-east direction. On the 28th, at 4 a.m., the same tidal phenomenon took place and lasted up to 7 a.m., but it was less intense, the alternate motions of the sea having only been observed four times. When day dawned on the 28th there was a peculiar crimson colouration from east by north to south-east by east, and the sun after rising showed as if seen through the red shade of a sextant.

At the Seychelles, at 4 p.m. on August 27, the tide came rushing in at the rate of about four miles an hour, and rose two feet. In about half an hour it receded; it returned and receded.

This continued all night and all next day, but the action was quicker and the rise lower. The observations were taken in a channel about twenty-three feet wide, and walled in on both sides. The action continued all day and part of the next day (29th), but not so frequently. At 5 p.m. on the 28th the sun was clear and bright. At sunset there was a lurid glare all over the sky; at 6.30 it was much brighter, and at 6.45 it disappeared. On the 27th the sky was slightly hazy all day. On the morning of the 29th the sun at 7 a.m. was more like a full moon than anything else, and appeared about 70° above the horizon, instead of as usual about 30°. At sunset on the 28th the sun looked as it does through a fog on a frosty day in England.

At Rodrigues, about 1.30 p.m. on the 27th, the sea was all disturbed, resembling water boiling heavily in a pot, swinging the boats which were floating about in all directions. It was then low tide, and most of the boats were aground. This disturbance in the water made its appearance quite suddenly, lasted for about half an hour, and ceased as suddenly as it had commenced. At 2.30 p.m. a similar disturbance commenced again in the inner harbour, and the tide all of a sudden rose to a height of 5 feet 11 inches, with a current of about ten knots an hour to the westward, floating all the boats which were aground, and tearing them from their moorings. All this happened in a very few minutes, and then the tide turned with equal force to the eastward, leaving the boats which were close inshore suddenly dry on the beach, and dragging the Government boat (a large decked pinnace) from heavy moorings, and leaving her dry on the reef. At noon on the 29th the tide was about its usual height and appeared to be settled. The water was very muddy, and not nearly so salt as sea water usually is; it was little more than brackish. Since this singular occurrence took place the sky at north-west has had in the evenings, to as late as 7.15 p.m., a very threatening and strange appearance of a deep purplish red colour.

Tidal disturbances were also observed on the west coast of Réunion, and especially at St. Pierre, on the south-west coast. The maximum amplitude (in height) of this tide was about a metre and a half. The flow took scarcely five minutes to rise, after which the water remained about a minute at rest, and then receded with the same rapidity, to rise again a minute after.

At East London (South Africa) it was not low water on August 27 till 6.29 p.m. At 5.30 p.m. on that day the tide-gauge showed 2 feet 3 inches, and the tide was running in fast. The gauge showed 3 feet 3 inches at 5.38; 1 foot 8 inches at 5.45; 1 foot 3 inches at 5.49; and 2 feet 3 inches at 6.10. Thus, although it was a falling tide, the water suddenly rose 1 foot in 8 minutes, then fell 1 foot 7 inches in 7 minutes, and 5 inches in the next 4 minutes, and then rose 1 foot in 21 minutes. The wind was moderate from east-south-east, and the barometer was 30·40, with dull cloudy weather to south-east. It had been observed during the early part of the afternoon that the tide was oscillating very considerably, and ebbing very fast for neap tides.

On Sunday, August 26, while coming through the Straits of Banca, Capt Strachan, of the s.s. *Anerley*, thought he heard in the forenoon a noise like that of distant cannonading; about noon the noise was more distinct, and it soon attracted the attention of all on board; flashes of light were seen to the south-westward. In the evening an arch of light rose in a short time from the horizon to the zenith. Three aneroid barometers on board rose and fell to the extent of nearly an inch at short intervals. During a part of Monday, the 27th, there was total darkness. Showers of pumice-stone lasted till midnight. The *Anerley* ran back and anchored under the North Watcher Island. While afterwards passing Anjer Point, it was seen that the lighthouse had disappeared, and that great damage had been done.

Capt. Perrot, of the French brig *Brani*, reports that on August 26 to 27, in 1° 39′ to 2° 59′ S. and 89° 56′ to 89° 50′ E. of P., constant peals of thunder were heard in the direction of Sumatra, but without any appearance of lightning in that direction. From midnight of the 27th to 11 a.m. of the 28th showers of "very white and very fine sand fell all over the vessel." More sand fell later on in the day and on the 29th. This sand obscured the atmosphere. On August 28, in 8° 20′ S., and 92° 04′ E., "a great quantity of dust, supposed to be coral dust," fell on board of the *County of Flint*, and a specimen of the dust has been kindly presented by Capt. Rowland, the master of that vessel. On September 9, in 4° 57′ S. and 79° 46′ E. of P., the French bark *Gipsy*, Capt. Martin, "encountered during the whole day a great bank of floating pumice-stone." On Sunday, August 26, in 0° 32′ S., and 105° 57′ E., Capt. Knight, of the brig *Airlie* heard, about 3 p.m., explosions, like the sound of heavy artillery, which continued at intervals till about 10 p.m., the last report making the ship tremble all over. Next morning the rigging and deck were covered with fine gray sand like dust.

Mr. Meldrum remarks that there is no doubt that the tidal disturbances observed at Mauritius and elsewhere in the Indian Ocean were due to earthquakes. The origin of the seismic waves was apparently in the Straits of Sunda, and at a very considerable depth below the surface. There were earth-waves, forced sea-waves, and aërial waves. The destruction in Java was caused, apparently, by an immense wave of translation. The extraordinary sunrises and sunsets observed at Mauritius, Rodrigues, and the Seychelles, were probably due to the sun's light passing obliquely through fine volcanic dust floating in the air. It is not improbable that the disturbances of the magnets on August 27 were due to electric currents produced by the action of subterranean forces.

THE LITERATURE OF THE FISHERIES EXHIBITION

FROM the moment of its inauguration, the present Exhibition has been the centre of a ceaseless activity, and we doubt if its streaming thousands of visitors have realised the amount of real work which has gone on in their presence. The results of this, embodied in an extensive literature, are now before the public, and add another testimony to the faultless management of the governing body. The enormity of the fishing interest and the need of reform in certain of its branches, are obvious; and now that the press is speculating upon the "outcome" of this great enterprise, all eyes are turned upon the executive. The extent to which the Exhibition is under State control is in itself a guarantee of success, and we hail with pleasure that same system of descriptive labelling of the exhibits, and the publication of authentic treatises upon or cognate to them, so long characteristic of the adjacent National Museum. By this system the public nets a tangible result—a knowledge of that which is at stake—becoming thus prepared to form a rational estimate of the final issue.

Of these treatises or "Handbooks"—also introductory to the more important "Conference Papers" to be spoken of hereafter—twelve have been already published, and it is to be regretted that they were not ready upon the opening day. Foremost among them is a powerful treatise on "The British Fish Trade," by His Excellency Spencer Walpole, whose authority in these matters no one will venture to doubt. Here at the outset, we encounter, in the deplored absence of reliable statistics, one of the most formidable difficulties of the whole question, and the labour under which the author has collected those upon which he so ably generalises, speaks for itself. It is shown that the East Coaster, Manxman, and Cornishman are—for obvious reasons—gradually monopolising the "take," and in the discussion upon and ultimate denunciation of the "brand" question, every thoughtful reader will agree. That a legal reform is pending no one will doubt, and such statements as those on p. 3 regarding the registration of boats, and on pp. 17 and 19 concerning the regulation of lights, suffice to show how the follies of this world can confound its administrative wisdom. This admirable work is a masterly analysis of the "catch and distribution," and should be read by all who would grasp the question in hand.

Dealing with the purely legal aspect, Mr. F. Pollock produces an authoritative work on "The Fishery Laws." The freshwater fisheries are seen to be, of necessity, more protected by law than those of the sea, territorial waters excepted; and it is important to note the extent to which conservators and other local authorities are empowered. The present aspect of the question is ably summed up in the author's "conclusion" to this a concise and well-arranged work.

The educational side of the matter has not been overlooked. In the production of a valuable little work on the zoology of food-fishes, Mr. G. B. Howes has successfully solved the very difficult problem of so diluting a large store of special knowledge, as to present it in a form well adapted to the assimilation of the class of readers for which it was avowedly written; and at the same time has contrived to invest it with an earnestness of tone and a dignity of conception which cannot fail to be productive of good to the most casual student. We cannot expect a composition of this kind to assume the accurate character of a text-book, and hence a few omissions, which more mature reflection would have remedied, constitute faults which should readily be overlooked. Altogether the author may fairly be congratulated on having scored a genuine success. Mr. W. S. Kent has done good service by bringing into one volume a synopsis of the distinctive characters of *every species* of British fish. His work, welcome for this reason alone, also embodies observations upon fishes in captivity, made during his career as naturalist to various existing aquaria. Many of them are interesting, but those upon the feeding of fishes must not be taken as necessarily indicative of their natural habits. The strange, guarded mode of progression of the Boar-fish, John Dory, and others described, can also be seen in the Pike in his native run. Much of the controversial matter in this book, befitting a conference paper, would, so treated, have entailed a desirable curtailing of this, a popular work of reference.

Man's all-prevailing imagination is wisely checked in "Sea Monsters Unmasked," in which Mr. H. Lee collects the scattered literature of this subject, and puts in a strong plea for the "cuttle theory," of which he is a well-known champion. An able defence of Pontoppidan is maintained, and one novel record set forth in this work is the dissipation of superstition—the kraken of our childhood—by a bishop—a Norwegian however, and in the eighteenth century. The two last-named manuals are illustrated, and all concerned merit congratulation upon the production of such examples of xylographic art as cover pp. 18 and 21 of the latter work.

The four following volumes are devoted to the more practical side of the industry. Mr. E. W. Holdsworth gives an exceedingly clear and systematic account of "The Apparatus for Fishing," and by the use of well-chosen similes succeeds in making plain his descriptions of the most intricate apparatus. The advances dependent upon the introduction of the "ketch-rigged" boats must, as here set forth, impress the reader with the need and value of improved apparatus. From the manner in which the various topics are treated by so competent an author, the reader can form some definite notion of the real practical difficulties which our fishermen encounter. These and other like matters are also fully dealt with in the two following works, by Messrs. J. G. Bertram and W. M. Adams respectively. The former is a plea for "The Unappreciated Fisherfolk," and the latter deals with the "Fisheries and Fishermen of all Countries." Much fresh testimony to the antiquity of the industry and the remarkable community of its followers—wherever they are found—is brought forward in these two volumes. Their hard-worked lives are shown, as generally acknowledged, to bring in but a scanty remuneration, accompanied by ceaseless anxiety and danger: how far the former is not at times due to their inherited conservatism—especially as regards the bait question—remains uncertain. The moral attributes of their lives, often untainted by "civilisation," are fully attested, and any one who has witnessed the operations incident upon, say, a Scotch herring take, will know that reform in this respect is more needed among the "gutters" and others accessory to the work than among the fishermen proper. The evidence adduced here and elsewhere points to a need of immediate reform in the apprenticeship question, much that is bad in it being due to existing regulations. The sketch given of the decay of the Irish fisheries is to be deplored, but of their restoration a hope still lingers. It is certain that if our fisherfolk "know nothing whatever about fish, except the way to catch them," they know this at least thoroughly. Mr. Adams claims for Oppian the dignity of an ichthyologist, and gives Ælian perhaps more than his due on p. 16 of his book. An incident, bearing upon the foundation of "Holland's Maritime Ascendancy" (p. 37), will not fail to interest our readers at the present time, and we note that neither Mr. Adams' researches nor those of any one else, have yet satisfactorily cleared up the origin of trawling.

It is not reassuring to compare the state of affairs in India, as detailed in Dr. Day's Manual, according to which, matters in that land stand as much in need of reform as at home. The author attributes the existing deplorable condition of the Indian fishermen largely to misrule, but more especially to the weight of the salt-tax imposed by the British; indeed, this topic is the refrain of the whole book, and the author's own investigations go far to support the belief. As might be expected, there are some curious customs and forms of apparatus described, in use among men so interesting as these from an ethnological point of view. Some speculations on p. 37 as to the behaviour of ova in mud are at least suggestive as our knowledge stands, and it is sincerely to be regretted that we have no British representative of the air-breathing Ophiocephalicæ described on p. 31, for if so, we venture to say that reform in the matter of our freshwater-fisheries would be less slow. Dr. Day also furnishes a work on "Fish Culture," in which he gives a historical review of the different aspects of this subject, not altogether favourable to our own possessions. Bewailing the need of Governmental action, and deploring the lack of statistical evidence upon which to generalise, the writer has either collected or furnished a mass of information which will both enlighten the public and prove of service to the practical man. The style of this book is somewhat heavy, and might be improved by a little judicious thinning. Both Dr. Day's books are illustrated—in the case of the former somewhat unintelligibly. No one interested in fishing will regret the failure of an attempt (made, we believe, by the late F. Buckland) to acclimatise the Sheat-fish (Silurus).

Mr. C. E. Fryer, in his work on "Salmon Fisheries," throws some doubts upon the necessity of elaborate artificial breeding, in a weighty argument, having for its keystone the restoration of our waters by the removal of pollution. The intricacies of the vexed question in hand are admirably put before the reader, and the author shows that, in some cases, existing obstacles could be removed, or that at least considerate action could, if exercised at the right time, beneficially modify the present state of affairs. In a comparison of the "pass" and "dam" systems, the success of Cooper's pass, on the Ballisodare River, Ireland, is adduced as a strong argument for the salmon-ladder. The reported death, after spawning, of the kelts of British Columbia opens up a new field for inquiry; and those interested in animal intelligence, so much discussed in these pages, will find here some interesting additional testimony to the capacity of the salmon. The author's description of the dawn of life on pp. 13 and 14 might be advantageously improved.

The only remaining volume, one by Mr. J. P. Wheeldon, treats of "Angling Clubs and Preservation Societies"; and in tracing the growth of many of these it is shown that they have done good work, as, for example, the abolition of "snatching" and "night-lining." The opening remarks, however, are not favourable to the majority of those in London, whose members unfortunately constitute more than ninety per cent. of our Thames angling-community. In tracing the changes wrought in our local waters, the village poacher of old is compared with the modern steam launch as a destroyer, and one more protest against the latter is lodged by the writer, a champion in the cause. It is important to note that the best regulated waters are those in which the management is vested in the hands of resident local bodies.

Such are these "Handbooks," the main portion of a series which will doubtless form a complete, but none too hopeful, epitome of the subject-matter. We now turn to the "Conference Papers."

The meetings at which these were read and discussed were all thrown open to the public, and, what is of greater importance, there were to be found present influentials of all grades and nationalities from royalty down to the very fishermen and dealers whose immediate interests were under discussion. The chair was invariably occupied by some one of authority—in one case by a sole living "Minister of Fisheries."

Of the masterly inaugural address delivered by Prof. Huxley, and of the paper by H.R.H. the Duke of Edinburgh, which formed the subject of the first sitting, the public have already been fully informed, and no one who was present at either of those meetings could fail to observe that the surroundings augured at least an active future. Concerning the address, suffice it to say that the truth of the only statement upon which dissension has been raised—by a carping minority who have entirely misunderstood the real meaning implied—has been more fully verified at each subsequent sitting (we refer to the inexhaustibility of the herring-fisheries). The very fact that in the latter admirable paper an attempt has been made to estimate *for the first time* our national take of fish—615,000 tons per annum—to say nothing of other statistics, gathered with immense labour, is in itself sufficient to justify immediate action, striking as it does at the very root of the evil at present existing—at the same time forming a good starting point for future investigation.

Beyond the formal passing of a vote of thanks, these were both dismissed without discussion, that upon the latter being adjourned *sine die;* but the subject-matters of the twenty-six papers which follow on were all freely discussed, both the length of the paper itself and of each speaker's remarks being under control, such as favoured a thorough sifting and all-round investigation of the topic under consideration—the object being to get at facts rather than to frame schemes. The Exhibition itself shows the far-reaching interests of the fishing industry, but in the account which follows we have attempted to roughly classify the work done in conference.

The gravity of the important question of "supply" will be seriously increased should the ingenious argument advanced by Sir H. Thompson on pp. 14 and 15 of his "Fish as Food" be substantiated. This paper is of great value, embodying as it does the most recent analyses in the question, of which it must be admitted that very little is known, and dissipating certain cherished but fallacious notions, in matters dietetic. Deploring our national indifference to these, the author formulates them for all conditions of men, on the supposition that fish shall be eaten, giving some valuable hints for practical treatment. It is well known that the West Highlander would probably rather starve than eat the eel which abounds in his waters, and which, the experienced author of this paper shows, supplies the very requisites of which he most stands in need.

Of first importance among a series of papers dealing with our home sea-fisheries is that on "The Herring Fisheries of Scotland," by Mr. Duff, M.P. Certain aspects of this question have been before the public for some time past, but the conclusions drawn by the writer all point to the introduction of improved apparatus and harbour accommodation, and to the repeal of any restrictive legislation which may exist in this—a matter in which the current official report shows that we do not know sufficient of the habits of the fish themselves to even account for their movements, still less to legislate upon their capture. This paper will be of great value to the practical fisherman, and furnishes a good survey of all sides of the industry. No greater argument for improved tackle can be adduced than that of the change wrought in our herring fisheries by the substitution of cotton for hemp netting. The closely allied "Mackerel and Pilchard Fisheries" form the subject of a thoroughly practical paper by Mr. T. Cornish, himself a worker. In the absence of statistics to prove otherwise, reform points in the same direction as for the herring-fisheries. Fuller information on the question and probable cause of the fluctuations in the "boat-side" price of mackerel (p. 10) would be acceptable. Although the habits of the pilchard baffle us, the author shows that where these fishes do occur they are most productive, and giving some interesting statistics concerning them, he advocates the establishment of a cheap market for their sale. In the discussion which follows, Prof. Brown Goode gives a short but interesting account of the American mackerel-fisheries. Two short papers on "Trawling" and "Line Fishing," respectively by Messrs. A. W. Ansell and C. M. Mundahl, embrace all the information upon our sea-fisheries other than that given above. Our readers are doubtless aware that a Commission is now inquiring into the disputes between the advocates of these two great systems, and much of the matter contained in these papers is naturally devoted to them. An amount of useful statistical information is collected, and certain subsidiary questions are discussed in their bearing upon the industry, notably those connected with transport. The old belief that the beam-trawl displaced and destroyed the ova of our deep-sea fishes has been but recently shattered by Sars, but Mr. Ansell adduces evidence to show that the question of shore-trawling demands investigation. There can be no reasonable doubt but that trawling will be the fishing of the future; it gives constant employment for the whole year, all objections raised against it are dissipated, and its advance must be sought in the application of steam power. It will be generally admitted that our existing home-difficulties are in no way due to defective apparatus.

Capt. Temple, in writing on "Seal Fisheries," adopts the wise course of holding himself responsible only for those of which he has had actual experience, leaving a hiatus, filled in during discussion by Mr. Martin and others. Devoting but little attention to the legal aspect of the industry, which we venture to say stands, with us, sorely in need of reform, the author seems more hopeful than the world at large of the chances of the chase. The body of the paper sets forth the *modus operandi* of the unenviable life of the sealer, whose lot entails great hardship, often rendered none the less buoyant for an excess of oil, nor the less happy under a "truck system." More might have been said with regard to this industry.

Turning now to other countries, we have most prominent a highly important paper on "The Fishery Industries of the United States," by Prof. Brown Goode. Some idea of its contents will be formed when we say that it fully bears out the impression made by the magnificent exhibits of that country, to study which delegates have even been sent over from other lands. The paper is a mine of useful information, and the refreshing speeches which have fallen from its author during the Conference meetings have shown how much remains untapped. The accounts given of refrigerator-cars, special oyster-trains, of the utilisation of waste, and the well-known potting system on the economic side; of floating hatcheries, of the artificial propagation of fish (twenty-seven species), and other practical topics; and on the administrative side, of the amount of liberty allowed in matters where a more jealous State might interfere, surely point to a common moral. The history of the Menhaden fishery cannot fail to strike all readers as an example of what can be done by persevering in a "new departure," and it is important to note that the system of management and insurance of the boats composing the American fishing fleets is such as to give every impetus to the work by arousing the best interests of the men, at the same time insuring those of the capitalist. The statements advanced in both this and a paper on the Canadian fisheries, by Mr. L. Z. Joneas, are based upon deductions from a most perfect system of registration. The status of the latter country—jealous of its reputation—in fishing matters is everywhere recognised, but even it has to record the failure of attempts to artificially cure the cod—the staple fish of its trade—and the writer deplores, for good reasons, the want of export traders in this the leading enterprise of its fishing population. The herring and mackerel fisheries are also dealt with, and it is reassuring to us to read that for the regulation of its lobster fisheries, of ten years' standing, Government measures are still being taken. The written account of the seal fishery conveys a good notion of its importance and a far better one of its technique than do certain sanguinary models exhibited in the Newfoundland section. The method of working a steam service on a wage system (in connection with their Great Lake fisheries) is worthy of attention.

Coming nearer home, Prof. Hubrecht, on behalf of the Dutch Government, tenders some very valuable observations upon the "Oyster Culture and Fisheries in the Netherlands." Upon the present state of *our* oyster-beds no comment is needed, any more than upon the fruitless efforts on the part of private individuals to establish new fisheries in our own waters. The experimental evidence—the result of observations still going on—brought forward by the author is of the highest importance; statistics favourable to artificial culture are given, the period of sexual maturation has been determined, and these and other similar facts ascertained all point to the conclusion drawn, viz. that "a close time *may* be of service, but that the great thing appears to be to leave a fair portion of the oysters on or around a natural bed wholly undisturbed for a series of consecutive years." This fact, discovered by chance in the Netherlands, embodies the sense of a statement made by Prof. Huxley in the matter in his opening address. It is noteworthy that the purely scientific biological and physico-chemical aspects of this question have received their full share of attention.

The main question bearing upon Mr. C. Harding's paper on "Mollusks" is that of bait. As the matter stands, action would be premature, until it can be shown that other forms of bait than those now in use are of no avail. It is well known that, on the one hand, fishermen are often compelled to stay on shore for want of bait, and on the other, it must be remembered that they are as conservative in this matter as in any which concerns them; but the fact that under *like circumstances* the Lofoden Islanders carry on a brisk catch by aid of the "gill-net," must not be overlooked.

(*To be continued.*)

THE PARIS OBSERVATORY EQUATORIAL[1]

THE accompanying illustration represents the remarkable apparatus recently set up in the Observatory of Paris, to which we have before called attention, the ingenious construction of which is due to M. Lœwy, sub-director of that establishment. Begun under the administration of M. Delaunay, interrupted during the war, thanks to a new act of munificence on the part of M. Bischoffsheim, it has now been finished.

To answer the requirements of modern astronomy equatorials are necessarily gigantic. Like the guns of modern warfare, each new apparatus is constructed on a larger scale than that of its predecessors, though it is not for purposes of destruction that they are aimed at the celestial bodies.

The advantages of the new equatorial are (1) that it measures great angular distances; (2) that it enables observations to be made with comparative ease and rapidity. Seated on a fixed chair apart from the support of the instrument, the astronomer is as if placed before his writing-table. The instrument obeys him, not he the instrument.

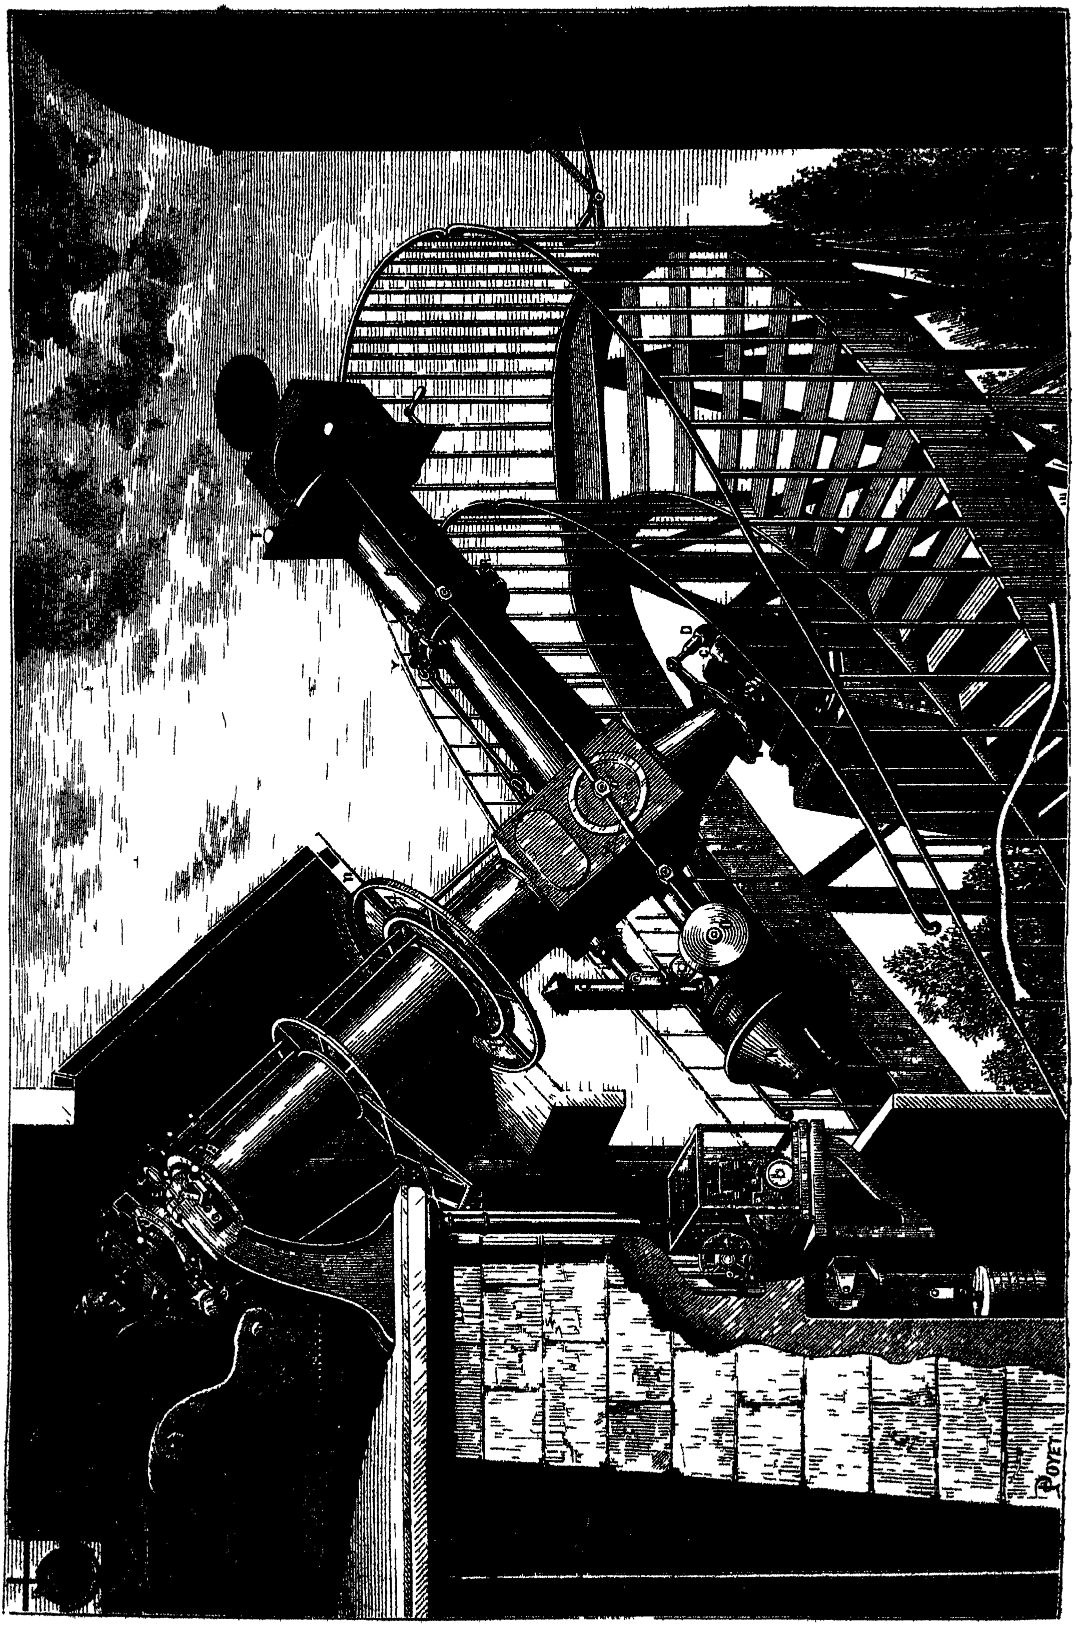
The new telescope is bent at right angles, one part directed in a line with the axis of the earth, and capable of turning round itself; the other perpendicular to it, and therefore moving in the plane of the equator. At the extremity of the latter is a mirror, and at the elbow of the telescope, in the interior, another mirror, both forming with the axis an angle of 45°. These mirrors are intended to reflect to each other, and finally to the observer seated with his eye at the eyepiece, the image of the star which is the object of observation.

The loss of light from successive reflections is hardly perceptible. The deformation which the images might suffer from the use of mirrors of insufficient thickness has been guarded against. In its optical qualities, too, the new equatorial is not surpassed by any telescope in the Observatory. Two advantages have thus been secured—the power of measuring great angular distances, and that of exploring the entire heavens, the observer regulating the apparatus himself, and not needing to shift his position.

Another benefit resulting from these happy arrangements must also be mentioned—the abolition of the Observatory with a heavy, ungainly, and expensive dome, and the substitution of one of much smaller compass and of much simpler construction. It consists of a movable part covering the object-glass end, and of a fixed part appropriated to the observer. When proceeding to make observations the

---

[1] From *La Nature*.



The New Bent Equatorial at the Paris Observatory observer draws away the movable part, which readily rolls on a railway. The extremity of the telescope bearing the mirror of the objective is thus left uncovered, while the astronomer, ensconced in his fixed part as in his own room, and sheltered from all inclemencies of weather, studies the infinitely great in conditions as comfortable as those of the naturalist who examines under his microscope the infinitely little.

Seeing it is but just that those who bear the burden should also enjoy the honour, we again state that the optical part of this instrument has been executed by the Brothers Henry, and the mechanical part by MM. Eichens and Gauthier.

THE INSTITUTION OF MECHANICAL ENGINEERS

THE Institution of Mechanical Engineers have held their autumn meeting this year in Birmingham—a town which for many years was the headquarters of the Society. The returning to their former seat was specially opportune, because the first paper on the list related to one of the greatest of Birmingham worthies, viz. James Watt. The title of the paper was "On the Inventions of James Watt, and his Models preserved at South Kensing- and Handsworth." The author is Mr. Edward A. Cowper, who, from his long connection with engineering both personally and through his father and uncle, is perhaps as well fitted as any man in England to trace out the course of Watt's inventions. This he has endeavoured to do, using as his main guide the numerous models preserved partly at the South Kensington Museum, partly at the Patent Office Museum, and partly at James Watt's house at Handsworth in Birmingham. Some of the models at South Kensington were in danger of falling altogether to pieces from dry rot and decay, but owing to the exertions of Mr. Sandham, the curator of this department, they have, as far as possible, been repaired; whilst, in addition, a complete set of photographs has been taken, which, even if the models themselves should cease to exist, would preserve their appearance and construction to future ages.

The sequence of James Watt's inventions with regard to the steam engine is stated at the end of Mr. Cowper's paper as follows:—

Firstly, in 1769 he made an invention (the separate condenser) which was practically an improvement on the Newcomen engine, the effect of which was to work pumping engines more economically and quickly.

Secondly, in 1781 he produced rotative power for driving factories, obtaining it in a manner by having a heavy balance weight to act one way whilst the steam acted the other way; however, the obtaining rotative motion by steam was an enormous advantage, far greater in its effect, in the author's opinion, than the improvement in the pumping engine.

Thirdly, the crowning invention of 1782 made the steam engine the one useful motive power, by making it double-acting and fit to drive cotton mills, flour mills, and all other machinery requiring regular rotative motion.

These various stages are illustrated by the models above mentioned. It is indeed doubtful whether there exists at present any model embodying the first idea of the separate condenser; but there is a most interesting model at South Kensington showing the condensation of steam in a separate surface condenser, composed of a large number of vertical tubes and provided with an air pump. This form of condenser, which in many cases, such as marine engines, has superseded all others, is thus proved to have been invented by James Watt, and not only invented, but brought to a high degree of perfection. The arrangements in this model, according to Mr. Cowper (than whom there can be no better authority), are in points equal to the best modern examples of surface condensation.

The only model actually exhibited was an engine of the character of Watt's patent of 1771. It is single acting, and has an open-topped cylinder, air pump, and condenser. There is a heavy bob on the connecting rod, which is used to help the piston up, while the vacuum formed below it causes it to descend on the return stroke, thus obtaining rotative motion. This engine, however, has a crank, and it is known that for many years Watt was afraid to use the crank in his engines, as it was supposed to be barred by another patent: it is true that his patent of 1771 shows a crank composed of a pin in a disk, but this is carefully termed "the point of attachment of the connecting rod." In practice, however, he used other methods, chiefly the well known sun and planet motion. Of this there are several different forms, which are illustrated by models at South Kensington. There is also a device consisting of a long rack or ladder fixed to the end of the connecting rod and digging into the teeth of a spur wheel on the engine shaft; the rod being guided by means of rollers running in a guide plate, so as to keep it in gear throughout the revolution.

Turning now to the 1782 patent, we find what Watt describes as "the new improved engine, the piston of which is pressed forcibly both upwards and downwards by the power of steam," that is to say, the engine is no longer single-acting, but double-acting. Here the chain hitherto used between the piston-rod and beam is replaced by a parallel motion, and the engine takes very much the form which was still common for shop engines within recent years. A good model of such an engine exists in the South Kensington Museum.

Some variations of this engine, probably made subsequently, are also illustrated by models, such as the Bull engine, in which the piston-rod passes out through the bottom of the cylinder, and takes hold of a beam placed lower down.

Still more interesting are Watt's proposals to make use of the expansion of steam for the saving of fuel; a diagram in one of his specifications shows that he fully understood this action, and he gives several methods by which the load upon the piston may be varied so that when the pressure is least it shall have least work to do. One of these is to mount a weight high up above the beam, which would be lifted when starting from either end of the stroke, and fall after passing the centre; this has been used even in recent times with good results. Several miscellaneous inventions of high interest are also described; one of these is the well-known invention of the steam indicator in probably its earliest and rudest form. Another is a counter for telling the revolutions of an engine, of which an actual specimen in good preservation remains in the Patent Office Museum.

There is also an arrangement for obtaining rotary motion in opposite directions out of the same engine by means of two connecting rods starting from a cross-head at one end of the beam, but working opposite ways. Another model shows two hammers worked by a single engine, the one lifted from the belly like an ordinary forge hammer, and the other by depressing the tail like a tilt hammer. A yet more curious device is a semi-rotary engine, of which an unfinished model remains in the Watt Room at Heathfield Hall. Here there is a piston fixed in a radial line to the shaft, within a large disk or cylinder. Inside this cylinder, at one part, is a fixed support, against which the steam presses each way as it acts against the piston, in either one direction or the other. The reciprocating shaft was made to act by a spur wheel on two racks attached to the pump rods. Watt also invented a very simple form of rotary engine, which, as Mr. Cowper states, has probably been reinvented at least fifty times since 1782, the year of his patent.

This leads us to notice the Watt Room, or attic workshop of James Watt, which still remains at Heathfield Hall precisely as he left it—his lathe and bench standing at the window, his tools lying about, and his old leather apron hung on the vice. There are numerous shelves with drugs and parcels on them, chiefly relating to his invention of copying-ink, and nests of small drawers full of tools; but the principal objects which strike the attention are two large machines for copying sculpture, whether in marble, alabaster, or wood. One of them copies to the exact size of the original, but the other is a reducing machine, taking a copy on a very reduced scale. The construction of both machines is described in the paper, and bears testimony to the inventive and mechanical genius of James Watt. The principle in each case consists in using a bar or slide, having at one end a blunt point to feel over the surface of the model, and at the other end a quick-running drill to cut away the surface of the material operated on. This drill is worked by a light cord attached to an ordinary foot lathe, whilst the bar, by means of a skilful arrangement of trussed frames, is made movable in any direction as the feeler passes over the model. The model and work can also be rotated, so as to be set at an angle for handcutting, &c. The drills and cutters, of which a large number are preserved, are excellent in their design and workmanship. These machines were apparently the amusement of Watt's late years, and are frequently referred to in his correspondence. They were never protected in any way, and partly perhaps for that reason have never been followed up and brought to perfection.

The second paper read was a report by the Research Committee on Friction. The Institution experiments on friction, which have been long delayed, have at length been carried so far as to admit of the publication of an interim report, prepared by Mr. Beauchamp Tower, which proves to be of great interest. They are, properly speaking, experiments on *lubrication*, being conducted on a 6-inch steel shaft or journal, which could be run at any given velocity, and on which rested a brass bearing carrying a loaded frame. By altering the load on this frame the pressure per square inch on the brass could be altered; and the temperature could also be altered by means of gas jets under the journal. As a standard of comparison experiments were first tried with the underside of the journal running in a bath of oil, so as to give the maximum of lubrication. The results of these experiments were to show that the friction of bearings under such circumstances follows the laws of liquid rather than (as usually assumed) of solid friction. These laws are very different. Solid friction varies directly as the pressure per unit of area, is independent of velocity at low speeds (Morin), but decreases with increasing velocity at high speeds (Galton, &c.). Liquid friction, on the other hand, is independent of the pressure per unit of surface, is directly dependent on the extent of surface, and increases as the square of the velocity. In fact it is not friction at all, but the shearing of one part of a more or less viscous fluid across another, as the above law plainly indicate. Now the Institution experiments show that, in the case of oil-bath lubrication, there is really a film of liquid oil surrounding the journal and keeping it away from the brass; and that what is called journal friction is really the shearing of one part of this film over the other. In such cases the friction may be exceedingly small: in some of these experiments it actually was as low as 1/1000th, and 1/500th is easily attained. This is much below what is generally supposed to obtain. The limit of pressure appeared to be about 600 lbs. per square inch. Beyond this the oil is squeezed out, and the metal "seizes." This is of course with high speed and constant pressure; with low speeds and intermittent pressure (as was pointed out in the discussion) very much higher pressures are admissible.

So far the experiments were satisfactory; but when the oil-bath was replaced by ordinary modes of lubrication, great difficulties were experienced. When the oil was introduced from above through grooves in the brass, it was found that, however these were cut, and at whatever part of the brass then opened, the bearing seized at a comparatively low pressure. The fact that such methods do as a matter of fact answer with ordinary railway vehicles is accounted for, it is supposed, by the end play of such bearings, and probably also by the general vibration. When, however, a pad fed with oil by capillary attraction from a bath below, was placed below the journal, so as to press lightly against it, satisfactory results were obtained, although the lubrication was so slight as only to appear to the touch as a slight greasiness. The laws here, however, approximated to those of solid friction, and probably the oil merely acts to fill up the little inequalities of the metal, and so practically render it smoother.

A curious subsidiary result should be noticed. When the oil-bath experiments were in progress, advantage was taken of the brass being removed to drill a hole in it for the subsequent tests with ordinary lubrication. On resuming the running, however, the oil was found in the hole, and on a pressure-gauge being attached, the finger rose to above 200 lbs. per square inch, which was the limit of its indications. This pressure was above the *average* pressure on the brass, and shows clearly that the surfaces are separated by a continuous film of oil, having at each point an actual hydrostatic pressure due to the external pressure which obtains at that point.

On the whole, these experiments, while to a great extent confirming the well-known researches of Prof. Thurston in America, throw a good deal more light on the curious phenomena and laws of journal friction. Their results (including some on temperature, which was found to have a marked influence in diminishing friction) are contained in a series of tables, which our space forbids us to publish, but which can no doubt be obtained, by any one interested, from the offices of the Institution, at 16, Victoria Chambers, Westminster.

NORDENSKJÖLD'S GREENLAND EXPEDITION[1]

II.

IN my report of the expedition of 1870 I drew attention to a clayey mud which is found in circular cavities, from one to three feet in depth, on the surface of the inland ice, not only near the shore, but even as far inland as we reached on that occasion. My companion on that occasion, Prof. Berggren, discovered that this substance formed the substratum of a peculiar[2] ice-flora, consisting of a quantity of different microscopical plants (algæ), of which some are even distributed beyond the clay on the ice itself, and which, in spite of their insignificance, play beyond doubt a very important part in nature's economy, from the fact that their dark colour far more readily absorbs the sun's heat than the bluish-white ice, and thereby they contribute to the destruction of the ice-sheet, and prevent its extension. Undoubtedly we have, in no small degree, to thank these organisms for the melting away of the layer of ice which once covered the Scandinavian peninsula. I examined the appearance of this substance in its relation to geology, and demonstrated:—

1. That it cannot have been washed down from the mountain ridges at the sides of the glaciers, as it was found evenly distributed at a far higher elevation than

---

[1] Continued from p. 23.

[2] Lately described by Prof. V. Wittrock. "Om Snöns och Isens Flora, Särskildt i Arktiska Trakterna." Ur "A. E. Nordenskjöld, Studier och Forskningar föranledda af mina resor i höga Norden." (Stockholm, 1883.) See NATURE, vol. xxviii. p. 304.

that of the ridges on the border of the glaciers, as well as in equal quantity on the top of the ice-knolls as on their sides or in the hollows between them.

2. That neither had it been distributed over the surface of the ice by running water, nor been pressed up from the hypothetical bottom "ground" moraine.

3. That the clay must therefore be a sediment from the air, the chief constituent of which is probably terrestrial dust spread by the wind over the surface of the ice.

4. That cosmic elements exist in this substance, as it contained molecules of metallic iron which could be drawn out by the magnet, and which under the blowpipe gave a reaction of cobalt and nickel.

Under these circumstances the remarkable dust which I have named "kryokonite," *i.e.* ice dust, obtained a great scientific interest, particularly as the cosmic element, viz. the matter deposited from space, was very considerable. Even later students who have visited the inland ice have observed this dust, but in places surrounded by mountains from which it might with more probability have been washed down. They have, therefore, and without having examined Prof. Berggren's and my own researches of 1870, paid little attention to the same, while the samples brought home by Dr. N. O. Holst from South Greenland in 1880 were not very extensive.

But now Dr. Berlin brings home from a great variety of places ice algæ, which, I feel convinced, will contribute fresh materials to our knowledge of the flora of the ice and snow. For my own part I have re-examined my first researches of the kryokonite, and they are fully corroborated. Everywhere where the snow from last winter has melted away, a fine dust, gray in colour, and, when wet, black or dark brown, is distributed over the inland ice in a layer which I should estimate at from 0·1 to 1 mm. in thickness if it was evenly distributed over the entire surface of the ice. It appears in the same quantity in the vicinity of the ice border surrounded by mountains as a hundred kilometres inland, but in the former locality it is mixed with a very fine sand, gray in colour, which may be separated from the kryokonite. Further inland this disappears, however, completely. Gravel or real sand I have never, in spite of searching for them, discovered in the kryokonite. The kryokonite always contains very fine granular atoms, which are attracted by the magnet, and which, as may be demonstrated by grating in an agate mortar and by analysis under the blowpipe, consist of a gray, metallic element, viz. nickel iron In general the dust is spread equally over the entire surface of the ice; thus it was found everywhere where the snow from the previous year had melted away, while, to judge by appearances, there seemed to be little difference between the quantity found near the coast and in the interior. The dust does not, however, form a continuous layer of clay, but has, by the melting of the ice, collected in cavities filled with water, which are found all over the surface. These are round, sometimes semicircular, one to three feet in depth, with a diameter of from a couple of millimetres to one metre or more. At the bottom a layer of kryokonite one to four millimetres in thickness is deposited, which has often, by organisms and by the wind, been formed into little balls, and everywhere where the original surface of the ice has not been changed by water-currents the cavities are found so close to each other that it would be very difficult to find a spot on the ice as large as the crown of a hat free from them. In the night, at a few degrees below freezing point, new ice forms on these hollows, but they do not freeze to the bottom even under the severest frost, and the sheet which covers them is never strong enough to support a man, more particularly if the hole is, as was the case during half our journey, covered with a few inches of newly-fallen snow.

The kryokonite cavities were perhaps more dangerous to our expedition than anything else we were exposed to. We passed, of course, a number of crevasses without bottom as far as the eye could penetrate, and wide enough to swallow up a man, but they were "open," *i.e.* free from a cover of snow, and could with proper caution be avoided, and the danger of these could further be minimised by the sending of the two-men sledges in front, and if one of the men fell into the crevasse he was supported by the runners and the alpenstock, which always enabled him to get up on the ice again. But this was far from being the case with the kryokonite hollows. These lie, with a diameter just large enough to hold the foot, as close to one another as the stumps of the trees in a felled forest, and it was therefore impossible not to stumble into them at every moment, which was the more annoying as it happened just when the foot was stretched for a step forward, and the traveller was precipitated to the ground, with his foot fastened in a hole three feet in depth. The worst part of our journey was four days outward and three days of the return, and it is not too much to say that each one of us during these seven days fell a hundred times into these cavities, viz. for all of us 7000 times. I am only surprised that no bones were broken, an accident which would not only have brought my exploration to an abrupt close, but might have had the most disastrous consequences, as it would have been utterly impossible to have carried a man in that state back to the coast. One advantage the kryokonite cavities had, however, viz. of offering us the purest drinking-water imaginable, of which we fully availed ourselves without the least bad consequences, in spite of our perspiring state.

On July 16 we covered thirteen, on the 17th eighteen and a half, and on the 18th seventeen and a half kilometres. The country, or more correctly the ice, now gradually rose from 965 to 1213 metres. The distances enumerated show that the ice became more smooth; but the road was still impeded by the kryokonite cavities, whereas the rivers, which even here were rich in water, became shallower, but stronger, thus easier of crossing. Our road was, besides, often cut off by immense snow-covered crevasses, which, however, did not cause much trouble.

On the night of the 18th, when arrived at camp No. 14, the Lapp Anders came to me and asked if he might be permitted to "have a run," viz. to make a reconnaissance on "skidor,"[1] to see if there was no "land" to the east. This granted, he started off without awaiting supper. He came back after six hours' absence, and reported that he had reached 27 kilometres further east, that the ice became smoother, but was still rising, but there was no sign of "land." If his statement was true, he had, after a laborious day's journey, in six hours covered about sixty kilometres! At first I considered his estimate exaggerated, but it proved to be perfectly correct. It took us thus *two whole* days to reach as far as he had got, as shown by the track in the snow. I particularly mention this occurrence in order to show that the Lapps really did cover the estimated distance of their journey eastward, of which more below.

During these days we passed several lakes, some of which had the appearance of not flowing away in the winter, as we found here large ice blocks several feet in diameter, screwed up on the shore, which circumstance I could only explain by assuming that a large quantity of water still remained here when the pools about became covered with new ice. The lakes are mostly circular, and their shores formed a snow "bog" which was almost impassable with the heavy sledges.

On July 19 we covered seventeen and a half, on the 20th sixteen and a half, on the 21st, seven, and on the 22nd seven and a half kilometres (15th to 18th camp). The ice rose between them from 1213 to 1492 metres. The distances enumerated fully show the nature of the ice. It was at first excellent, particularly in the morning, when the new snow was covered with a layer of hard ice; but on the latter days we had great difficulty in proceeding, as a sleet fell with a south-east wind in the night between the 20th and the 21st. The new snow, as well as that lying from the previous year, became a perfect snow bog in which the sledges constantly stuck so that it required at times four men to get them out. We all got wet, and had great difficulty in finding a spot on the ice dry enough to pitch the tent. On the 22nd we had to pitch it in the wet snow, where the feet immediately became saturated on putting them outside the indiarubber mattresses. A little later on in the year, when the surface of the snow is again covered with ice, or earlier, before the thaw sets in, the surface would no doubt be excellent to journey on.

---

[1] [The Swedish "skidor" and Norwegian "Ski," are long strips of pinewood slightly bent at the top, polished and as elastic as if they were of the finest steel, with a strap for the feet in the centre, on which the Lapps and Scandinavians run on the snow with remarkahle agility at a tremendous pace.—ED.]

When we, therefore, on July 21, were compelled to pitch the tent in wet snow, as no dry spot could be discovered, and it was impossible to drag the sledges further, I sent the Lapp Lars Tuorda forward on "skidor" to find a dry road. He came back and stated that the ice everywhere was covered with water and snow. For the first time in his life he was at a loss what to suggest. It being utterly impossible to get the sledges further, I had no choice. I decided to turn back.

I wished, however, to let the Lapps go forward some distance to the east to see the country as far as possible. At first I considered it advisable to let their journey only last twenty-four hours, but as both Anders and Lars insisted that they were most eager to find the "Promised Land," and said they could do nothing towards discovering it in that short period, I granted them leave to run eastwards for four days and nights, and then return.

On leaving I gave them the following written orders:—

"Instructions for Lars and Anders's 'skid' run on the inland ice of Greenland, viz.:—

"Lars and Anders have orders to proceed on skidor eastwards, but are allowed to alter the course, if they may deem it advisable, to north or south.

"At the end of every third mile the barometer shall be read and the direction run noted.

"The absence is to be four days, but we will wait for six days. After that, viz. on the morning of July 28, we return. If not returned, we leave behind in a sledge provisions, brandy, mattresses, &c.

"Lars is warned not to be too bold. Should land be reached, you are to collect as much as you may gather of blossoms and grass, if possible several kinds (specimens) of each.

"Given on the inland ice in Greenland, July 21, 1883,
"A. E. NORDENSKJÖLD"

They were allowed to select what provisions, &c., they desired, and were furnished with two compasses, aneroid barometers, and a watch.

At 2.30 a.m. on July 22 they started. The days we waited for them were generally spent in the tent, as water surrounded us everywhere. The sky was covered with a thin veil of clouds, through which the sun shone warmly, at times even scorchingly. From time to time this veil of clouds, or haze, descended to the surface of the ice and hid the view over the expanse, but it was, remarkably enough, not wet but *dry*, yes, so dry that our wet clothes absolutely dried in it. We have therefore, I consider, witnessed a phenomenon on the inland ice of Greenland which is related to the "sun-smoke" phenomenon of Scandinavia, viz. what Arago has described under the name "brouillard sec."

On the 24th, after an absence of fifty-seven hours, the Lapps returned. It was the want of drinking-water and fuel which compelled them to return. The surface had been excellent for their journey, and they had covered a distance out and back of 230 kilometres, an estimate which I consider perfectly reliable. During the march forward the barometer was read every third hour. It gave the point of return a height of 2000 metres.[1]

As to the run, Lars rendered the following report: When they had reached thirty miles from the camp no more water could be found. Further on the ice became perfectly smooth. The thermometer registered – 5° C. It was very easy to proceed on the "skidor." At the point of return the snow was level and packed by the wind. There was no trace of land. They only saw before them a smooth ice covered by fine and hard snow. The composition of the surface was this—first four feet of loose snow, then granular ice, and at last an open space large enough to hold an outstretched hand. It was surrounded by angular bits of ice (crystals). The inland ice was formed in terraces—thus, first a hill, then a level, again another hill, and so on. The Lapps had slept for four hours, from twelve midnight on July 23, in a hollow dug in the snow while a terrific storm blew. They had till then been awake for fifty-three hours. On the first day there was no wind, but next day it came from the south, and lasted thus until twenty-four miles on the return journey, when it changed to west. On the return journey, when forty miles from our camp, two ravens were seen. They came from the north and returned in the same direction. The Lapps had for a moment lost the track of the "skidor" in the snow. The ravens flew at first, they found, parallel with the track, and then turned to the north.

On July 25 we began the return journey. It was high time, as the weather now became very bad, and it was with great difficulty we proceeded in the hazy air between the number of crevasses. The cold, after the sun sunk below the horizon at night, also became very great; and on the morning of July 27 the glass fell to –11° C.

As to the return journey I may be very brief. The rivers now impeded us but little, as they were to a great extent dried up. The ice-knolls had decreased considerably in size too, and lay more apart, but the glacial crevasses had greatly expanded, and were more dangerous, being covered with snow. Even the cavities and the glacial wells, of which many undoubtedly leave a veritable testimony of their existence behind them in the shape of corresponding hollows in the rock beneath, had expanded and increased in number. On a few occasions, on the return journey, we saw flocks of birds, most probably water-fowl, which were returning from the north.

On July 31 we again sighted land, which was reached on the afternoon of August 4, and proceeded to "Sophia Harbour," where Esquimaux were, as arranged, waiting for us. For convenience sake I now divided our party into two, one of which sailed in the lifeboat of the *Sophia* to Egedesminde, where the steamer was to take us on board, and the other, in which was myself, marched to that place across the low but broad promontory which separates Tessiusarsoak and South-East Bay, and then in two Esquimaux "Kone" boats to Ikamiut and Egedesminde.

On August 16 the *Sophia* arrived from the north, embarked us, and made for Ivigtut, where we arrived on the 19th.

Of the expedition carried out under Dr. Nathorst during my absence he will himself make a report,[2] and I have no doubt that the results of the same will prove very important. Particularly will the very rich collections of fossil plants, which he has made with the greatest regard to the geological condition of the strata, be of great value to science, as they will furnish us with many new materials and detailed illustrations of the flora of the Far North during the epoch when forests of fig-trees, cycadi, ginko, magnolia, and tulip-trees covered these regions. Dr. Forsstrand and Herr

---

[1] I have as yet been unable to verify the barometer calculations, and the figures stated here may suffer some modification.

[2] NATURE, vol. xxviii. p. 541.

Kolthoff's collections and studies of the fauna of Greenland will also contribute to extend our knowledge of the naturalistic conditions of the Arctic regions, while the careful researches made by Herr Hamberg of the saltness, composition, and temperature of the sea will, I am sure, greatly benefit hydrography. His researches have been effected in Davis Strait and Baffin's Bay too, the hydrographical conditions of which are but little known.

With regard to the results of my exploration of the inland ice, I may be permitted to say a few words. That we found no ice-free land in the interior, or, that it does not exist between 68° and 69° lat. in Greenland, is due directly to the orographical conditions which exist in this part of the country, as referred to in my programme of the expedition.[1] The land has here the form of a round loaf of bread, with sides which gradually and symmetrically slope down to the sea, *i.e.* exactly the shape which I then pointed out was a necessary condition if the entire country should be covered with a continuous sheet of ice.

But, thanks to the Lapps, my expedition is the first which has penetrated into the very heart of the enormous Greenland continent, and which has thus solved a problem of the greatest geographical and scientific importance. It is the first exploration of the hitherto unknown interior of Greenland, the only continent in the world into which man had not penetrated.

A new means of locomotion, the "skidor," seems also to have been acquired for the Arctic explorer of the future, which may greatly assist him in his work, and enable him to reach places hitherto deemed impossible of approach, but of the use of which the Lapp seems to possess, so to speak, the monopoly.

A. E. NORDENSKJÖLD

We are enabled to supplement Baron Nordenskjöld's report by the following account, furnished to us by another member of the expedition, of the visit paid to the remarkable Igaliko ruins:—

On August 24 the *Sophia* steamed to Igaliko, at the bottom of the fjord of the same name. The object of this visit was to examine the ancient Norse ruins which are found here. Those who thus believe that the "Österbygd" of Greenland was situated in this part assert that the ruins of Igaliko are nothing more nor less than those of Erik Röde's own mansion "Brattelid." However that may be, the Norseman who selected this spot for his residence acted very wisely. The ruins are situated at the very bottom of the fjord, where the absence or presence of the ocean ice on the coast affects the climate but little. The vegetation in this spot is, in consequence, quite luxuriant. Thus a vaginal plant, *Lathyrus maritimus*, grows here in such abundance that it reminds one of a field of peas, while *Ranunculus acris* attains a height of two feet, and *Campanula rotundifolia*, the bluebell, along with various grasses, flourish in great profusion. In the pools Menyanthes and Potamogeton thrive, while copses of birch-trees and willows offer excellent fuel. There are also plenty of wild berries. The ruins, the walls of which were formed of enormous blocks of sandstone, lie just below a table-shaped ridge of sandstone by the side of a crystal brook, copiously encircled by *Alchemilla vulgaris* and watercress. The spot is, in fact, one which would fully justify the name given to the country. At the time of our visit about a dozen cows were fed here, whose excellent milk we tasted, while in the beds around the huts of the natives swedes and potatoes grew luxuriantly, the former having attained the size of large apples. It certainly was strange to view this spot, and we naturally asked each other, what has become of the old Norsemen who once peopled it? It is impossible to believe that they were extirpated or conquered by the Esquimaux. It seems far more probable that both races have commingled, an assumption further corroborated by the strange circumstance that Esquimaux are found in this tract who have never been in contact with the Danes, but who nevertheless possess features of pure Norse character.

THE VIENNA INTERNATIONAL ELECTRIC EXHIBITION

(FROM OUR VIENNA CORRESPONDENT.)

THE Scientific Commission having for its purpose the taking of electrical measurements and conducting scientific researches at the Exhibition commenced its work on September 17. By the assembled Austrian and foreign delegates Prof. Stefan (Vienna) was elected president, while as vice-presidents were elected Prof. Galilei Ferraris (Turin), Col. J. Florensoff (St. Petersburg), Prof. Hauffe (Vienna), Prof. Kittler (Darmstadt), Major A. Obermayer (Vienna), Sir William Siemens (London), Prof. Mascart (Paris), Emil Effendi Lacoine (Constantinople), Prof. E. Gerard (Liége). The Commission is subdivided into the following eight sections according to the matters to be dealt with:—1. Scientific instruments. 2. Motors and general mechanics. 3. Dynamo-electric machines, electric lighting, and transmission of power. 4. Electro-chemistry. 5. Telegraphy, telephony, electric bells and clocks. 6. Signalling for railways and military purposes. 7. Electro-therapeutics. 8. Application of electricity relating to arts, industry, and technology. At the third section the measurements are carried out according to the plans devised for electric measurements by the president of the section, Prof. Kittler, and for photometric measurements by Prof. Voit (Munich). A control calibration of the instruments used in this section showed their accuracy and precision, as well as the correctness of the hypothesis that the variations of the earth's magnetism during the daily periods of measuring could not exert any important influence on the results of the measurements. When the first trials were made, some disturbances of the delicate instruments arose, the cause being that the iron building of the Rotunda was charged with electricity by the return currents of the dynamo-electric machines. But this difficulty was soon overcome by modifying the arrangements of the conducting wires, and the Commission is now hard at work trying the various electric lamps and machines. The results of these trials when finished will be published by the Commission. The series of lectures delivered at the theatre of the Exhibition is still continued, and we had occasion to hear, among others, Mr. Preece (who spoke in English), on the recent progress of telegraphy in England, and the Austrian professors Mach, Zenger, Pfaundler, Waltenhofen. The attendance on the part of the public is as large as it was at the Universal Exhibition in the year 1873, the average number of visitors being 15,000 daily.

While in the Bernstein lamps described in our last letter a relatively thick carbon is used, in the Cruto lamps brought to the Exhibition a few days ago a very fine but hollow carbon loop is employed; it is prepared by a process similar to that already devised by Mr. Sawyer in the year 1878 for flashing carbon filaments. A thin platinum wire (1/20 mm. to 1/60 mm. in diameter) is heated, by an electric current passing through it, in a vessel containing the vapour of a hydrocarbon. The hydrocarbon being decomposed in a short time, the platinum wire is covered by a homogeneous layer of deposited pure carbon. The platinum is then removed by volatilising it. The remaining hollow carbon filaments thus obtained are very fine and elastic, and show a metallic polish. The Cruto lamps, as well as a series of Lodiguine incandescent lamps, are fed by Gravier's distributers of electricity, the installation of which has been completed during the past week. The process of preparing the illuminating portions of the new incandescent lamps with high resistance exhibited by Siemens and Halske, and lighting beautifully Witzmann's restaurant and the exhibits of this firm, is still kept secret. The stall of the Société Anonyme d Électricité is lighted by several Gerard incandescent lamps of high candle-power (300 candles). These lamps have large ovoid glass bulbs pierced at their broad part by a narrow glass tube containing the two terminals of the conducting wires. The five straight and comparatively thick carbon rods forming the illuminating part of the lamp are cemented together at their ends by means of a carbonaceous paste in such a manner that, by the two pairs of longer rods being connected by a short intermediate carbon rod, two long-sided, acute-angled triangles crossing one another are formed, which, if brought to incandescence, make the appearance of a single flame, giving an agreeable and bright light. This chain of carbon rods is fastened to the supporting terminals by two short cylindrical pieces of carbon. An interesting historical collection of incandescent lamps is exhibited in the Prussian Section, showing the lamps made by Florensoff, Buliguine, and Khotinsky in the years 1872 and 1873. The latter had already used exhausted glass bulbs, but the carbon rod used having a diameter of 1·5 mm. to a length of 1½ cm. could not give a good result.

---

[1] NATURE, vol. xxviii. p. 37.

Most of the incandescent lamps exhibited have transparent bulbs, and very disagreeable after images of the glowing carbon filaments are caused if they are looked at only for a moment or two.

An interesting and practical regulator for single incandescent lamps has been exhibited by the International Electric Company. By turning a handle the intensity of incandescence can be raised or lowered. This regulating apparatus consists of a hollow perforated brass bulb mounted below the lamp, containing a number of carbon disks, which, when the handle is right over in one direction, are highly compressed, a metallic circuit being established at the same time. By turning the handle, the metallic circuit is broken, and the current passes through the carbon disks, while the pressure on them being gradually relaxed causes a steady increase of resistance to the current, thus diminishing its intensity, and in the final position the circuit is broken, and the carbon filament of the lamp ceases to glow.

Vienna, October 16

NOTES

We have received the following announcement from the Royal Society:—On the last day of the present month the Fellows of the Royal Society will hold their anniversary meeting, and elect Council and officers for the ensuing year. The following list has been nominated:—President: Prof. Thomas Henry Huxley, LL.D.; Treasurer: John Evans, D.C.L., LL.D.; Secretaries: Prof. George Gabriel Stokes, M.A., D.C.L., LL.D., Prof. Michael Foster, M.A., M.D.; Foreign Secretary: Prof. Alexander William Williamson, LL.D.; other Members of the Council: Capt. W. de Wiveleslie Abney, R.E., Prof. W. Grylls Adams, M.A., F.C.P.S., the Duke of Argyll, K.T., D.C.L., John Gilbert Baker, F.L.S., Thomas Lauder Brunton, M.D., Sc.D., William Henry M. Christie, Astronomer-Royal, William De la Rue, M.A., D.C.L., Sir Frederick J. O. Evans, K.C.B., Prof. George Carey Foster, B.A., Francis Galton, M.A., F.G.S., James Whitbread Lee Glaisher, M.A., Sir William Withey Gull, Bart., M.D., Hugo Müller, Ph.D., Prof. Joseph Prestwich, M.A., F.G.S., Prof Osborne Reynolds, M.A., Osbert Salvin, M.A., F.L.S. It will be a subject of congratulation to the scientific world at large to learn from the above announcement that Prof. Huxley has consented to allow himself to be nominated for President.

A notice of some importance has just been issued by St. John's College, Cambridge. Inasmuch as it indicates an advance on the old examination in mathematics and classics only, which has hitherto obtained at this college, we are glad to welcome the change. It will tend to place science candidates still more on an equality with those who pursue the older studies, and it will directly encourage them to undertake "independent" work (the word is better than "original" where Bachelors of Arts are concerned) at the stage when they have most leisure and most plasticity. The notice is as follows:—"Candidates for Fellowships at the next annual election are invited to submit to the electors dissertations or other writings as evidence of their independent work, in accordance with the following directions:—(*a*) The matter and form of the writings to be left to the discretion of the candidates; (*b*) the writings may be prepared especially with a view to the election, or may consist wholly or partly of work already published; (*c*) the candidates to state clearly what parts of their writings they claim to be original; (*d*) the candidates to inform the Master not later than June 1 of the subjects of the writings they propose to submit; (*e*) the writings to be sent to the Master not later than September 1. The electors wish it to be understood that at the next election their decision will be influenced by consideration of the following points:—(1) The performance of the candidates in the University and other public examinations. (2) The quality and promise of the writings submitted by the candidates. Candidates may be examined by papers or *vivâ voce* on questions arising out of their writings, and on other matters also if the electors desire it. (3) The proficiency in some special subject of candidates who do not submit any writings. Such candidates may at their own request be examined in their special subject, provided they give full and precise information in regard to it by letter addressed to the Master not later than June 1. (4) The candidates' power of expression as shown in the composition of an extempore English essay. Candidates will be offered a certain number of subjects to choose from; and in judging of the essays account will be taken of method and style. (5) Such other evidence as may be forthcoming to attest the candidates' qualifications. The next annual election will take place on Monday, November 3, 1884. Candidates will be required to present themselves for examination on Tuesday, October 21, at 9 a.m."

The success which attended the course of lectures delivered this year has induced the Council of the Institution of Civil Engineers to make arrangements for a similar series next session. Electricity was then dealt with. Another most important subject will now be treated, namely, "Heat in its Mechanical Applications." The lectures will be delivered on Thursday evenings at 8 p.m., in the months from November to April, as under:—1883: November 15, "The General Theory of Thermodynamics," by Prof. Osborne Reynolds, F.R.S.; December 6, "The Generation of Steam, and the Thermodynamic Problems Involved," by Mr. W. Anderson, M.Inst.C.E.; 1884: January 17, "The Steam-Engine," by Mr. E. A. Cowper, M.Inst.C.E.; February 21, "Gas- and Caloric-Engines," by Prof. Fleeming Jenkin, F.R.SS.L. and E., M.Inst.C.E.; March 20, "Compressed-Air and other Refrigerating Machinery," by Mr. A. C. Kirk, M.Inst.C.E.; April 3, "Heat-Action of Explosives," by Capt. Andrew Noble, F.R.S., M.Inst.C.E.

The 130th Session of the Society of Arts will commence on the 21st inst., with an opening address from Sir William Siemens, the chairman of the Society's Council. Previous to Christmas there will be four ordinary meetings, in addition to the opening meeting, and for these the following arrangements have been made:—November 28, A. J. R. Trendell, "The International Fisheries Exhibition of 1883;" December 5, Thomas T. P. Bruce Warren, "The Manufacture of Mineral Waters;" December 12, Thomas Fletcher, F.C.S., "Coal Gas as a Labour-saving Agent in Mechanical Trades;" December 19, W. H. Preece, F.R.S., "The Progress of Electric Lighting." There will be six courses of lectures delivered during the session, under the bequest of Dr. Cantor. These will be: (1) "The Scientific Basis of Cookery," by W. Mattieu Williams, F.C.S.; (2) "Recent Improvements in Photo-mechanical Printing Methods," by Thomas Bolas, F.C.S.; (3) "London Houses," by Robert W. Edis, F.S.A.; (4) "The Alloys used for Coinage," by Prof. W. Chandler Roberts, F.R.S., Chemist of the Royal Mint; (5) "Some New Optical Instruments and Arrangements," by J. Norman Lockyer, F.R.S., F.R.A.S.; and (6) "Fermentation and Distillation," by Prof. W. Noel Hartley, F.C.S. The usual short course of Juvenile Lectures will be delivered during the Christmas holidays. The subject will be "Crystals and Crystallisation," and the lecturer Mr. J. M. Thomson, of King's College, London.

The death is announced of Prof. Peter T. Riess, whose treatise on frictional electricity—"Die Lehre von Reibungselektricität"—has long been a standard work. Riess was a careful and accurate observer of phenomena. His researches on ring-figures produced by discharges, on the electric air thermometer, and on the phenomena of the return stroke, are well known. His memoirs on electricity were published in a collected form some years ago.

The sum of 100*l.* has been placed at the disposal of the Council of the Statistical Society by Mr. H. D. Pochin for an essay in memory of the late Mr. Wm. Newmarch, F.R.S., "On the Extent to which Recent Legislation is in accordance with, or Deviates from, the True Principles of Economic Science; and showing the Permanent Effects which may be expected to arise from such Legislation." The Council accordingly invite public competition for the prize above mentioned. Essays must be sent in on or before May 1, 1884.

Dr. Sophus Tromholt has just left for Iceland, where he intends to establish his auroral station during the coming winter.

In connection with the vote given by the delegates to the congress at Rome for establishing a meridian common to all civilised nations, it may be stated that the first French meridian was not originally that of Paris and special to the French geographers, but Ferro, according to an ordinance of Louis XIII., published in 1632 in compliance with a report drawn up by Cardinal de Richelieu, then superintendent of commerce and navigation. It was transferred to Paris only fifty years afterwards by Dominique Cassini, who obtained the authorisation of Louis XIV. and the French Academy of Sciences, because it was too difficult to ascertain the exact distance of the Ferro meridian.

The date of admission of foundation members to the International Society of Electricians has been postponed to Nov. 15, when a general meeting to constitute the Society will be held, which at present numbers 900 members, belonging to twenty nationalities. Requests for admission should be addressed to M. Georges Berger, 99, rue de Grenelle, Paris.

M. Raphael Perulta writing to *La Nature* under date Manilla, September 14, states that the detonations of the Java eruption of August 27 were distinctly heard throughout the Philippine Islands; so distinctly were the sounds heard that gunboats were sent out under the impression that a fight was going on at Java, or that a ship in distress was firing for help.

Of the expeditions despatched in May last from Denmark to Greenland, the one to North Greenland, under Lieut. Hammers, has just returned, after having succeeded in accomplishing its object, viz. to map out and examine the coast from Ritenbank to Kongatsiok in the Egedesminde district, *viâ* Jacobshavn and Kristiansbank, between 70° and 68° 20′ N. lat. During the journey the finest weather prevailed, which was a necessary condition, as this part of the coast is greatly obstructed by islands and holmes, while there are but few heights along it. By Lieut. Hammers and his companions' labours the exploration of the coast of North Greenland has been completed, Lieuts. Steenstrup and Hammers having—between 1878 and 1880—explored the district between Pröven (Upernivik) and Godhavn, and Lieut. Jensen, in 1879, the coast between Holstensborg and Egedesminde. These expeditions have succeeded in collecting all the materials necessary for a map of the whole coast between Pröven and Holstenborg. Lieut. Hammers has, besides geographical researches, also made collections in natural history, and brought home valuable botanical and mineralogical collections. From the second expedition, under Lieut. Holm, despatched this summer to the district of Julianshaab in order to carry out a two-and-a-half years' exploration of the south coast of Greenland, a short report has been received, stating that it had arrived at Huilek, a small settlement on the east coast, in lat. 61°. Lieut. Holm had established a depot of provisions here, to be brought north next summer to his place of wintering. He intended to return to Nanortalik, on the west coast, between Julianshaab and Cape Farewell, this autumn, where the expedition will carry out meteorological and auroral observations during the winter, which would be a continuation on a small scale of those effected at Godthaab for a year under the international scheme. These observations will be carried on in the buildings erected there by Capt. Hoffmeyer in 1882, and with the instruments of the previous expedition. On returning to the west coast in the autumn, Lieut. Holm's expedition will effect detailed explorations of the coast, fjords, and the ice and sea. He has arranged with several Esquimaux to meet and assist him on his journey northwards next year, when he hopes to reach the sixty-seventh degree of latitude.

Mr. Carl Bock's new book is now nearly ready for publication. Its title will be "Temples and Elephants," a narrative of a journey of exploration through Upper Siam and Lao. Messrs. Sampson Low and Co. are the publishers.

During the last few years the Swedish Government have, as an experiment, retained an entomologist to assist farmers in the destruction of insects, &c., dangerous to the crops. The services of this functionary have, however, been in such request that the appointment is to be made a permanent one.

On October 26 at about 7 p.m. a splendid meteor was seen in the district of Hernösand, Sweden. A traveller on the road to Ragunda states that he suddenly saw the night lit up as in broad daylight, which was caused by a large meteor appearing with a blinding white lustre in the zenith and travelling very rapidly down to the horizon. When half way, as it appeared to the observer, between zenith and the earth it suddenly burst, throwing a quantity of sparks in every direction.

A Universal Exhibition on a tolerably large scale will be opened at Nice on December 1 next, and will continue open the whole of the winter. The Algerian *Akhbar* suggests that in 1885 a Pan-Mediterranean exhibition should be opened in Algiers, and in 1887 a Pan-African one.

We have to announce three new numbers of the "Encyclopædia of Natural Sciences" from the publishing house of Eduard Trewendt, Breslau—No. 35 of Part 1, and Nos. 17 and 18 of Part 2, making up altogether a substantial addition to what had been previously accomplished in the progress of this comprehensive work. No. 35, Part 1, gives a continuation of "Schenk's Manual of Botany," more particularly a paper by Göbel, well and copiously illustrated, on the "Comparative

History of the Development of Vegetable Organs." No. 17 of the second part of the total work concludes the first volume of the "Alphabetical Manual of Chemistry," edited by Ladenburg, and begins the second volume with a series of valuable articles; one by Biedermann, on the "Atmosphere," taking up by itself as much as two and a half printed sheets. No. 18 brings the "Alphabetical Manual of Mineralogy, Geology, and Palæontology" as far as the letter "I," and supplies treatises by Kenngott, Lasaulx, and Rolle. Lasaulx's work on "Glaciers" should, especially, be of interest.

"UNIVERSAL GEOGRAPHIES" are appearing on all hands. There is M. Reclus' magnum opus and Stanford's Compendium; a new edition of Balbi is appearing in Vienna, and we believe of Malte Brun in Paris. Now the first parts of an Italian "Universal Geography" have been sent us, "La Terra," by Signor G. Marinelli, and published by Dr. F. Vallardi of Milan. It begins at the beginning, with the earth as a member of the solar system, and enters into considerable astronomical detail, and into the composition of the sun and the results of recent solar research. It is abundantly illustrated, and seems to us to deserve a large circulation, which we hope it will have in Italy. We have also the first part of a new German work of this class, "Unser Wissen von der Erde, Allgemeine Erdkunde," edited by Drs. Hann, Baron von Hochstetter, and A. Pokorny. These names are a guarantee that this work will be up to a high scientific standard, and it is evident that scientific geography will occupy a large space. The illustrations are good. The publisher is Freytag of Leipzig.

MR. G. K. GILBERT has recently, according to *Science*, given some rather disturbing suggestions to the people of Salt Lake City (*Salt Lake Weekly Tribune*, September 20) concerning the probability of destructive earthquakes there. He describes the slow and still continuing growth of the ranges in the Great Basin by repeated dislocation along great fractures, the earth's crust on one side being elevated and tilted into mountain attitude by an upthrust that produces compression and distortion in the rocky mass, until the strain can no longer be borne, and something must give way. Suddenly and violently there is a slipping of one wall of the fissure on the other, far enough to relieve the strain, and this is felt as an earthquake; then follows a long period of quiet, during which the strain is gradually reimposed. Such a shock occurred in Owen's Valley, along the eastern base of the Sierra Nevada, in 1872, when a fault-scarp five to twenty feet high and forty miles long was produced. A scarp thirty or forty feet high is known along the western foot of the Wahsatch Range, south of Salt Lake, and other scarps of similar origin have been found at the bases of many of the Basin ranges. The date of their formation is not known; but it must be comparatively recent, because they are still so little worn away. Wherever they are fresh, and consequently of modern uplift, there is probable safety from earthquakes for ages to come, because a long time is needed for the accumulation of another strain sufficient to cause a slipping of one wall of the fissure on the other. Conversely, when they are old and worn down, the breaking strain may even now be almost reached, and an earthquake may be expected at any time. This is the case at Salt Lake; for, continuous as are the fault-scarps along the base of the Wahsatch, they are absent near this city. From the Warm Springs to Emigration Cañon they have not been found, and the rational explanation of their absence is that a very long time has elapsed since their last renewal. In this period the earth-strain has been slowly increasing. Some day it will overcome the friction, lift the mountains a few feet, and re-enact on a fearful scale the catastrophe of Owen's Valley.

[illegible]HE Aristotelian Society is exerting itself, we hear, to widen [illegible]phere of action, so that it may be to philosophy what the scientific societies are to science. Very encouraging support has already been obtained from those interested in philosophy and the relations between philosophy and science.

WE have received the first number of *The Science Monthly* (Bogue), neatly got up and well printed.

THE additions to the Zoological Society's Gardens during the past week include a Sykes's Monkey (*Cercopithecus albigularis*) from East Africa, presented by Mr. Thomas L. M. Rose; a Black-eared Marmoset (*Hapale penicillata*) from South-East Brazil, presented by Mr. S. Sandbach Parker; a Globose Curassow (*Crax globicera* ♀) from Central America, presented by Miss Beale; a Red-throated Diver (*Colymbus septentrionalis*), British, presented by Mr. T. E. Gunn; a Dwarf Chameleon (*Chamæleon pumilus*) from South Africa, presented by Capt. J. C. Robinson; a Common Heron (*Ardea cinerea*), European, a Common Cormorant (*Phalacrocorax carbo*), a Gannet (*Sula bassana*), British, deposited; a Common Otter (*Lutra vulgaris*), British, two Crested Screamers (*Chauna chavaria*) from Buenos Ayres, purchased.

OUR ASTRONOMICAL COLUMN

PONS' COMET.—We continue our ephemeris of this comet from the provisionally-corrected orbit of MM. Schulhof and Bossert :—

At Greenwich Midnight

On the evening of November 4 the comet as viewed in one of the larger-sized comet-seekers of Martins of Berlin, was conspicuous enough, with traces of a tail. On October 29 Mr. Talmage, observing with Mr. Barclay's 10-inch refractor at Leyton, considered it made about the same impression upon the eye as the annular nebula in Lyra.

TEMPEL'S COMET, 1873 II.—According to the calculations of M. L. Schulhof, of Paris, this comet will arrive at perihelion on the 20th of the present month. Its position on the evening of the previous day will be approximately in R.A. 18h. 33m., N.P.D. 114° 0′; distant from the earth 1·93, and from the sun 1·34, so that the theoretical intensity of light expressed in the usual way will be 0·15, under which condition it will be of the last degree of faintness, judging from the experience of 1878. Still as the comet sets more than 2h. 20m. after the sun, it would be well worth while to search for it where there is a clear sky near the horizon, especially in the South of Europe.

A NEW STAR CATALOGUE.—Prof. van de Sande Bakhuyzen states that the catalogue of positions of stars contained in the first sixty-six volumes of the *Astronomische Nachrichten*, commenced by the late Prof. Hoek and continued by Dr. Kam, formerly of the Observatory at Leyden, has been completed and is ready for the press. It contains the places of nearly 5000 stars reduced to 1855·0, with their annual precessions, and the secular variations, the epoch of observation, &c. It is not mentioned in what way the publication of the catalogue is to be effected.

THE OBAN PENNATULIDA[1]

THIS report is a very thorough piece of work. It consists of a detailed and finished description of specimens dredged during an excursion of the Birmingham Natural History Society in July, 1881. The specimens all belonged to the three species *Funiculina quadrangularis*, *Pennatula phosphorea*, and *Virgularia mirabilis*. The language in which they are described is very distinct and lucid, though perhaps some criticism may be allowed as to the scale of measurement used and as to a certain point in the nomenclature. Measurements are given in the decimal divisions of an inch, instead of the metrical system, which is so much more satisfactory. The axial portion of a Pennatulid is described as consisting of two parts—the stalk and the rachis, the latter being the polyp-bearing portion; and the word "stem" is used for the calcareous rod running through the axis of both rachis and stalk. "Stem" would naturally mean both the stalk and rachis together as opposed to the polyp-leaves. "Core" might be suggested as a better term for the axial skeleton. The example of Kölliker has been followed in the use of the terms "polyps" and "zooids" for the two kinds of individuals. In describing the "stomach," its inner lining membrane is called ectoderm, but no reference is made to he fact that the evidence for its being ectodermic is embryological.

The description and figures given of *Funiculina* are the first published in English which deal with the internal structure; and they are in some respects more complete and perfect than those of Kölliker in his monograph on the Pennatulida. The examination of the largest of the specimens, which was thirty-nine inches long, has finally disproved the validity of the distinction maintained by Verrill and Gray to exist between the Scotch *Funiculina*, and that of the Mediterranean and Scandinavia. The supposed species, *F. Forbesii*, is simply the younger form, the largest of the Oban specimens being in all respects a typical *F. quadrangularis*.

A very interesting part of the work is that which refers to the reproductive organs of *Pennatula phosphorea*; the male and female elements are here fully described and figured for the first time. The fact of the sexes being distinct was ascertained by Lacaze Duthiers, but neither he nor Kölliker give figures or satisfactory descriptions of the sexual organs. The male elements are shown here to be produced in spherical capsules, which at first sight resemble ova.

In the account of *Virgularia* the process of the origin of new polyps is described. The stomachs arise as invaginations of the surface of the rachis into the cavity of large canals lined by endoderm.

An ingenious discussion of the reason why specimens of *Virgularia* when dredged are almost always truncated at the upper end leads to the conclusion that the loss is due to the attacks of fish.

The descriptions are followed by a complete critical list of the literature, and an account of the geographical distribution both in the sea and in museums. The figures are very clear, and at the same time artistic. It is much to be regretted that the condition of the specimens did not allow the histology to be completely made out. No doubt the Birmingham Society will pay greater attention to the preservation of material for this purpose on future occasions.

J. T. CUNNINGHAM

NOTES FROM THE OTAGO UNIVERSITY MUSEUM

III.—*On some Embryos of "Callorhynchus antarcticus"*

SOME weeks since I obtained from a fisherman a number of eggs of *Callorhynchus antarcticus* from Wickliffe Bay, Otago Peninsula. As I believe this is the first time any observations have been made on the development of the *Holocephali*, the following report of remarks made at a meeting of the Otago Institute on May 7 may be of some interest to morphologists:—

"The eggs were found buried in the sand a little below low-water mark, a position which would seem to cast some doubt on the generally accepted theory which accounts for the peculiar form of the egg-shell by supposing it to have acquired a protective resemblance to kelp. The cavity for the embryo has an elongated pyriform shape, the broad end being anterior, and the narrower or posterior end produced into a long canal. On what may be described as the 'hairy' in contradistinction to the smooth side of the egg-shell, there is on each side of the middle line at the anterior end a longitudinal slit in the wall of the cavity, which serves to allow of currents to and from the latter for respiratory purposes. The anterior ends of these slits are united by a weak place in the wall of the egg-shell; very slight pressure from within causes rupture along this line and produces a valve, the lateral boundaries of which are formed by the respiratory slits, its anterior boundary by the line of rupture. This valve readily opens outwards by pressure on its inner face, and serves for the exit of the fœtus; pressure upon its outer face only forces it against the opposite wall of the cavity.

"The advanced embryo lies in the cavity in such a position that its head lies at about the level of the base or hinge of the valve, and therefore some distance from the anterior end of the cavity, its tail lies in the narrow posterior prolongation of the cavity, which fits it accurately; its right side lies almost invariably against the smooth, its left against the hairy side of the egg-shell.

"Unfortunately the embryos in all the four dozen eggs examined were in a tolerably advanced stage of development, so that there will be little chance of getting younger stages until next autumn. The youngest obtained are about four inches long; they have large yolk-sacs (1·75 inch in length), and very long external gills projecting from the opercular aperture; the snout has acquired the characteristic form, but the tail shows as yet no trace of heterocercality, nor the skin of the silvery character it has in the adult, being in the fresh state translucent and highly vascular. The yolk-sac is remarkable; it is longitudinally elongated, and produced into numerous blunt paired projections, which are tolerably constant in position; one pair of these always lies to the anterior end of the dorsal surface of the yolk-sac, and between them the snout of the embryo is invariably situated. The umbilical or somatic stalk is practically obsolete, the fœtus being sessile upon the yolk-sac.

"As in Elasmobranchs the yolk-sac is gradually drawn into the cœlome, and so consists in advanced stages of an internal and an external portion, the former continually increasing at the expense of the latter. As the external portion diminishes in size, it loses its blood-vessels, and its projections gradually disappear. In the latest stage obtained, the external portion is not more than 0·5 inch long, the internal portion being fully 1·25 inch in length, and causing a great distension of the abdominal walls. In this stage also, the external gills are absorbed, and the adult characters of the integument attained."

The foregoing description appeared in the *New Zealand Journal of Science* for this month.

T. JEFFERY PARKER

Dunedin, N.Z., July 13

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The delegates of the Common University Fund have agreed to appoint a Reader in Anthropology, so as to utilise the presence of Dr. Tylor for University instruction. In a Convocation to be held on November 15, a decree will be submitted to the House, fixing the Reader's stipend at 200*l*. a year, on condition that he lecture at least once a week in each of the three terms, and receive students for informal instruction and assistance.

A Scholarship in Natural Science is offered this term by Wadham College. Candidates may offer either Animal Morphology, Botanical Morphology, or Physiology. They will also be examined in Elementary Chemistry and Physics. Weight will also be given to a knowledge of French or German. Candidates must send in their names to the Warden on or before November 15.

CAMBRIDGE.—Dr. H. Sidgwick has been elected Knightbridge Professor of Moral Philosophy. Prof. Bonney, F.R.S., has been approved for the degree of Sc.D. Dr. Routh has been elected Hon. Fellow of Peterhouse; and Professors Dewar and M. J. M. Hill have been elected Ordinary Fellows. Messrs. A. G. Greenhill and R. R. Webb will be the Examiners in the Mathematical Tripos of 1874. The honorary degree of M.A. has been conferred on Prof. Macalister, F.R.S. Messrs. J. A. Fleming and S. L. Hart, both distinguished Natural Science graduates, have been elected Fellows of St. John's.

Dr. Gaskell, F.R.S., is to be approved as a Teacher of Physiology, Dr. F. Darwin as a Teacher of Biology, and Mr. G. B.

---

[1] Report by Prof. A. Milnes Marshall, M.D., D.Sc., and William P. Marshall. Birmingham, 1882.

Atkinson as a Teacher of Physics, for the purposes of medical education.

The honorary degree of M.A. is proposed to be conferred on Mr. A. Graham, First Assistant at the Observatory, in recognition of his astronomical services.

Mr. M. C. Potter of Peterhouse has been appointed Assistant Curator of the Herbarium.

Mr. W. H. Caldwell, Fellow of Caius College, has been appointed the first Balfour student.

At St. John's College, in December, there will be open for competition among students who have not commenced residence in the University—The Foundation Scholarships then vacant, two of which may, after residence is commenced, be increased in value to 100*l*. a year on condition of regular residence, satisfactory progress, and good conduct; four Minor Scholarships, two being of the value of 75*l*. a year and two of 50*l*. a year; three Exhibitions of 50*l*. a year for two years; one Exhibition of 40*l*. a year for four years; one Exhibition of 32*l*. a year for four years; together with two Exhibitions of 30*l*. a year for four years; one Exhibition of 33*l*. 6*s*. 8*d*. a year for three years. The number of Exhibitions may be increased if candidates of sufficient merit present themselves. The Foundation Scholarships and Minor Scholarships are open to candidates under nineteen years of age. The Minor Scholarships are tenable for two years, or until the Minor Scholar is elected o a Foundation Scholarship. The Exhibitions are open to all andidates irrespective of age, and are not vacated by the election of the Exhibitioner to a Foundation Scholarship. The umber of Foundation Scholarships is sixty. Candidates may present themselves for examination in any of the following subjects, namely, Classics, Mathematics, Natural Science, Hebrew, and Sanskrit. A candidate may be elected on the ground of proficiency in any one of these taken singly. The Examination in Natural Science will include papers and practical work in Physics, Chemistry, General Biology, Botany, Zoology and Comparative Anatomy, Human Anatomy, Physiology, and Geology. Every candidate must show a competent knowledge of two at least of the following subjects, namely: (1) Elementary Physics, (2) Elementary Chemistry, (3) Elementary Biology [the range of the examination in Elementary Biology may be taken as defined by the contents of Huxley and Martin's "Course of Practical Instruction in Elementary Biology" (Macmillan)]. A candidate may be elected on the ground of special proficiency in any one of the foregoing sciences. Each candidate's name should be sent not later than November 27, 1883, to the tutor under whom t is proposed to place him.

SCIENTIFIC SERIALS

THE *Journal of Physiology*, vol. iv. Nos. 2 and 3, August, 1883, contains: W. H. Gaskell, on the innervation of the heart, with special reference to the heart of the tortoise (plates 2 to 5). —J. Th. Cash, description of a double cardiograph for the frog's heart.—Wesley T. Mills, an examination of some controverted points of the physiology of the voice, especially the registers of the singing voice and the falsetto.—F. Warner, a method and pparatus for obtaining graphic records of various kinds of ovements of the hand and its parts, and of enumerating such ovements and their combinations (plate 6).—H. H. Donaldon and L. T. Stevens, the influence of digitaline on the work f the heart and on the flow through the blood-vessels.—G. F. o and Th. Cash, on the relation between the active phases of ntraction and the latent period of skeletal muscle.—S. Ringer, hird contribution regarding the influence of the inorganic contuents of the blood on the ventricular contraction.—L. C. ooldridge, further observations on the coagulation of the lood.—Also Supplement Part to vol. iv. Physiological papers f 1882.

THE *Journal of the Royal Microscopical Society*, October, 883, contains: On *Asplanchna ebbesbornii*, nov. sp., by E. T. Hudson, LL.D. (plates 9 and 10), with the usual bimonthly ummary of current researches relating to zoology and botany principally Invertebrata and Cryptogamia), microscopy, &c.

THE *American Naturalist* for October, 1883, contains: Man's lace in nature, by W. N. Lockington.—The Naturalist Bralian Expedition (No. 2, continued), the Lower Jacuhy and São ronymo, by H. H. Smith.—On the shells of the Colorado desert and the region further east, by R. E. Stearns (woodcuts). —Review of Report C_4 second geological survey of Pennsylvania, by Dr. P. Frazer.—Means of plant dispersion, by E. J. Hill.—Is the group Arthropoda a valid one? by J. S. Kingsley. —On the Serpentine of Staten Island, New York, and on a classification of the natural sciences, by T. Sterry Hunt.

Proceedings of the Linnean Society of New South Wales, vol. vii. part 4, 1883, contains:—E. P. Ramsay, on new species of Solea; contributions to Australian Oology, part 2; notes on birds from Solomon Islands.—E. Meyrick, Australian Microlepidoptera, Oecophoridæ.—Prof. Stephens, geology of the Western coalfields, parts 1 and 2.—Dr. J. C. Cox, edible Australian oysters.—C. W. de Vis, new birds of Queensland; description of a new Belideus from Northern Queensland; on two new Queensland fishes.—Rev. C. Kalchbrenner, *Fungi aliquot Australiæ Orientalis*, and on new species of Agaricus.—Rev. J. E. Tenison-Woods, botanical notes on Queensland; on a species of Brachyphyllum from mesozoic coal beds, Ipswich, Queensland.—Wm. Macleay, new fishes of New Guinea, No. 3. —Wm. A. Haswell, on *Phoronis australis*, n.sp.; an instance of symbiosis (an Actinia lodging in the pits of a species of Cellepora); segmental organs of Aphroditea.—On some new species of Australian tubicolous annelids (plate).—E. Haviland, plants indigenous to Sydney.—Rev. Dr. Woolls, Eucalypts first known in Europe.—J. J. Fletcher, comparative anatomy of the female urogenital system in kangaroos, part 1.—Dr. H. B. Guppy, habits of the Birgus of the Solomon Islands.

Vol. viii. part 1, June 19, 1883, contains:—William Macleay, a new form of mullet from New Guinea.—J. J. Fletcher, anatomy of the urogenital system of the kangaroos, part 2.— C. W. de Vis, extinct marsupial remains.—C. P. Ramsay, contributions to the zoology of New Guinea (plate, *Hapalotes papuanus*).—Some new Australian fishes.—H. R. Whittell, habits of *Pelopœus lætus*, and *Larrada australis*; on the voracity of a species of Heterostema.—Rev. J. E. Tenison-Woods, on the coal flora of Australia (eleven plates, heliotypes); gives a history of the subject and descriptive list of fossils (pp. 36-167).— Rev. B. Scortechini, contributions to the flora of Queensland.— Rev. C. Kalchbrenner, two new fungi.—Jas. Norton, fructification of the Bunya (*Araucaria bidwellii*) in Queensland.

Vol. viii. part 2, July 17, 1883, contains:—E. Haviland, plants indigenous to Sydney, Nos. 3 and 4.—C. W. de Vis, toothmarked bones of extinct marsupials; on *Brachalletes palmeri*, an extinct marsupial; on a lower jaw of *Palorchestes azael;* on some new genera and species of Australian fishes.—H. K. Bennett, habits of *Leipoa ocellata;* on water from Eucalypti roots.—Wm. Macleay, fishes from the Burdekin and Mary Rivers; New Guinea fishes, No. 4.—J. J. Fletcher, on a viviparous lizard (*Hinulia elegans*).—John Brazier, synonymy of Australian and Polynesian land and marine mollusca; localities of some species of recent Polynesian mollusca.—Rev. J. E. Tenison-Woods, mesozoic fossils from Central Australia (two plates).—Rev. B. Scortechini, second half century of plants new to South Queensland.

Revue Internationale des Sciences Biologiques for July, 1883, contains:—Elie Reclus, studies on indigenous people: the Khonds.—Prof. Huxley, living organisms and the way to study them (translated).—Proceedings of the Academy of Sciences, Paris.

August.—Leon Metchnikov, essay on the Christian communion: the God of Nyssa and the God of Nazareth.—Prof. Huxley, living organisms and the way to study them (translated).—Proceedings of the Academy of Sciences, Amsterdam, and of the Academy of Sciences, Paris.

September.—Prof. Huxley, living organisms and the way to study them (translated).—Prof. Williamson, the primitive ancestors of living plants and their relation to the doctrine of evolution.—Proceedings of the Academy of Sciences, Paris.

Atti of the Royal Academy dei Lincei, June 17.—Remarks on Schiff's memoir on changes of volume during fusion, by Sig. Camizzaro.—On De Stefani's upper crest of the Apennines, by S. Capellini and Taramelli.—On the temperature corresponding with the glacial period, by S. Pietro Blaserna. —On the measurement of altitudes by means of the barometer, by S. Paolo Busin.—On the isobarometric types of Italy, by the same author.—On the first phenomena in the development of the embryo of the Böops (*Salpa maxima*), by S. Francesco Todaro.—On the caloric developed in liquids by the discharge of electric condensers, by S. Emilio Villari.—Report on the antiquities recently discovered in Val della Torre, Adria, Forli, Orvieto, and other parts of Italy, by S. Fiorelli.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, October 29.—M. Blanchard, president, in the chair.—Allusion was made by the President to the loss sustained by the Academy in the person of M. Louis Breguet, the mechanician, who died suddenly on the night of October 26.—Observations on the geometrical deformations produced by pressure on a rectangular parallelopipedon with prolongation in a single direction (two illustrations), by M. Tresca.—Fossil and savage man; anthropological studies, by M. de Quatrefages. In presenting this important work to the Academy, the author remarked that since the discoveries of Boucher de Perthes and the jawbone of Moulin-Quignon some twenty years ago, not only has the existence of Quaternary man been universally recognised, but a certain number of distinct Quaternary races has already been determined. The existence of Tertiary man also, without being yet fully demonstrated, has been rendered highly probable, especially by the researches of M. Capellini. A detailed account is given of all the known Quaternary races of Western Europe, based mainly on the fossil remains collected by M. de Baye in the artificial caves explored by him in the department of La Marne.—Note on the freezing point of alcoholic solutions, by M. F. M. Raoult. In accordance with the general law established by the author, the soluble bases are shown to belong to two distinct groups, one presenting a molecular lowering of the freezing point comprised between 33° and 48°, with a mean of 39°; the other lying between 16° and 20°, with a mean of 19°.—Report on the results of the treatment of the vines attacked by phylloxera in the Maritime Alps, by M. Laugier. The report speaks favourably of the experiments made during the years 1881-83 with sulphuret of carbon and sulphocarbonate of potassium.—On certain equations connected with surfaces of constant curvature, by M. G. Darboux.—Determination of the equivalent of nickel by means of its sulphate, by M. H. Daubigny.—On a process for detecting by chemical analysis the traces of blood in clothes that have been washed, by M. C. Husson.—A comparative study of the excitability of the surface and deeper parts of the brain, by M. Couty.—On the spermatogenesis of podophthalmous crustaceans, and especially of the decapods, by M. G. Herrmann.—Note on the anatomy and physiology of the Sacculine and the allied genera Peltogaster and Lernæodiscus, by M. Yves Delage.

Berlin

Physical Society, October 19.—Dr. Frölich made a report on measurements of solar heat executed by him in continuation of observations he had made at an earlier date, according to the method he was still pursuing, on the temperature of celestial space. Observations on the temperature of the earth's surface had led him to the conviction that solar heat, the principal source of the temperature of the earth, must pass through very rapid oscillations, which were in all probability connected with the quick movements on the solar surface that had been brought to light by the new methods of investigation. To establish these variations beyond all doubt required long-continued observations of the sun's heat by means of trustworthy instruments remaining invariable for years. Thermoelectric piles provided with due protective apparatus could alone be deemed instruments of this description. Mr. Langley's bolometer was not adequate for any length of time, the electric resistance of thin metal plates being liable to very rapid variations. The thermoelectric pile he had made use of was inclosed in a wide, double-walled pipe, opening in front in the shape of a funnel, in which circulated a constant stream of water of atmospheric temperature. The exposed front end of the thermopile was closed by a plate of rock salt, and the whole was set up in such a manner that it could turn in a frame, which itself might be turned in all directions and closed by means of a Venetian shutter. The whole apparatus was capable of revolving in all directions. The thermopile and the galvanometer of Siemens and Halske's recent construction were perfectly trustworthy instruments, as Dr. Frölich had repeatedly convinced himself. There now remained the task of finding a standard for the solar heat. For this purpose preparatory experiments were instituted with luminous heat generators—a glowing platina sheet and an electrical glow-lamp of older construction. These experiments, however, came to nothing At last recourse was had to dark heat, such as was produced from a hollow screen filled with steam, one side o which is blackened with smoke, and the other whitene with chalk. With these apparatus measurements of sola heat were taken on perfectly clear days under a brigh sun at very different points of the sun's altitude, and were r presented by curves, the abscissæ of which showed the thicknes of the transmitted atmosphere; the ordinates, the observe warmth of the sun. Under favourable conditions the curv formed a straight line, which, when extended to zero of the abscissa, furnished the measurement of the solar heat withou atmospheric absorption. The measurements were at first attempted to be taken at the Berlin Observatory, but were foun to present so many irregularities and oscillations in consequenc of the situation of the Observatory in the midst of the city an the constantly vaporous and dusty state of the atmosphere surrounding it that they had to be discontinued there. Better an more regular results were obtained from observations made at house in the western suburbs. The best and most conclusiv measurements, however, in which the errors of observation wer reduced to 1 per cent., were obtained from a tower in the West En near Berlin, where, throughout six days of the past summer, curves were registered approximating very closely to a straight line. On single measurement executed on the Faulhorn at a height of 900 feet yielded a perfectly straight curve. The six measurement distributed over the months of June, July, August, September, and October, showed considerably different results in the different months. Dr. Fröhlich caused Dr. Lohse, who had bee taking daily photographs of the sun at the Potsdam Observatory, to supply him with data regarding the presence of sunspot in the last months. From these data Dr. Fröhlich found tha the lower degrees of solar heat corresponded with numerou formations of spots, while the higher gradations of hea were attended with fewer sunspots. In this coincidence Dr. Frölich was disposed to see a sequence of cause and effect. It would be necessary, however, to accumulate a large number of observations, and in particular to take them at elevated stations before any definitive judgment could be passed respecting the influence of sunspots on solar heat.

THURSDAY, NOVEMBER 15, 1883

THE "AUSTRAL" JUDGMENT

THE inquiry into the sinking of the mail-steamer *Austral* in Sydney Harbour has probably attracted more attention than any other case which has come before the Wreck Commissioner's Court since it was established. Not merely those specially interested in or connected with shipping but the public generally were desirous of knowing how it happened that a magnificent steamship of the most recent construction should have foundered at anchor in smooth water and in a dead calm. It is satisfactory, therefore, to find that the causes of the accident have been discovered, and that they do not affect the reputation of the ship, nor the credit of her designers. The circumstances of the accident are briefly these:—The *Austral* had completed her second outward voyage, had discharged nearly all her cargo, and had partially refilled her coal-bunkers. A collier came alongside to continue the coaling, and the work was proceeded with during the night. In order to facilitate coaling, and to keep the interior of the ship clean, coal-ports had been formed in the sides, the height of these ports above water when the ship was upright being about five feet. The coaling was rapidly done, and no proper supervision was exercised by any of the officers of the ship; consequently a considerable weight of coal was introduced on the starboard side without any corresponding weight being placed on the port side, and the ship was gradually heeled over. At length such an inclination was reached that the sills of the after coaling-ports were brought to the sea-level; water began to enter the ports and to pass freely into the interior of the ship, and in fifteen to twenty minutes from the time the alarm was given she sank. No one appears to have observed the dangerous proximity of the coal-ports to the water until it was too late to save the vessel. Had there been ordinary care and watchfulness the accident would not have occurred.

This last statement can be made with certainty in view of the scientific evidence respecting the stability of the *Austral* given in the course of the inquiry. After the vessel had been raised and brought home the owners commissioned a competent naval architect, Mr. Elgar, to thoroughly investigate her conditions of stability at the time of the accident, and under various circumstances. As a basis for this investigation an inclining experiment was made on the vessel, and the vertical position of her centre of gravity was ascertained. Simple calculations enabled the investigator to pass from the experimental condition of the ship to all other conditions brought under review, and to place before the Court ample materials for answering the question—Was she a stable vessel? This answer was distinctly in the affirmative; indeed there is no room for doubting that with proper management, and the occasional use of the water-ballast with which she was provided, the *Austral* possessed sufficient stability. It is unnecessary to enter into details as to her "stiffness" and range of stability in various conditions of lading; but it may be worth stating that, according to the evidence, had the coal-ports been closed and all weights on board secured, she would have been practically *uncapsizable* at the time of the accident.

It would be out of place here to discuss the finding of the Court as regards the responsibility or blameworthiness of the owners, officers, and other persons connected with the management of the ship. One broad general principle laid down by the Commissioner in his judgment may be considered with propriety, since it affects not merely the owners of the *Austral*, but shipowners as a body. Mr. Rothery is strongly of opinion that shipowners should cause investigations to be made of the stability of their ships, and should furnish captains with the results of these investigations for information and guidance. In the case of the *Austral* no such investigations were made until after the accident, and what happened with her is the common case with ships of the mercantile marine. There has been a remarkable advance in the applications of scientific methods to merchant-ship construction of late years, and the consideration of problems of stability has been forced upon the attention of shipbuilders and shipowners in many cases. But the adoption of the Commissioner's opinion would involve a much greater extension of scientific method and exact calculation than has yet taken place.

Shipbuilders necessarily have no control over the loading of the ships they build; and in most merchant ships the stability is practically determined by the nature and distribution of the cargoes carried. Up to the present time exceedingly little information is on record as to the actual stability of laden merchant ships; and their loading usually has to be done under very hurried and difficult conditions by men possessed of great practical experience, but having little or no acquaintance with the principles of stability. Owners have hitherto been content to depend almost exclusively on experience with previous vessels in determining the dimensions of new ships, and have not set much store on the result of scientific calculation. Builders, on the other hand, recognising their want of control over the working of the vessels, have refrained, for the most part, from making detailed calculations of stability. Even the leading firms have chiefly confined attention to experimental and other investigations which would be useful in preparing subsequent designs; and in most cases the owners have not had communicated to them any facts which may have been ascertained respecting the stability of ships. Mr. Rothery maintains that all this should be changed: that fuller investigations should be universally made, and the results furnished by the owners to the captains.

The great, if not paramount, importance of due consideration being given to the stability of merchant ships, and particularly of cargo-carrying steamers, is recognised by the most eminent authorities. Mr. Rothery in his recommendation indorses what has been said and written repeatedly of late years. But while there is a very general assent to the proposition that something should be done to secure a due amount of stability and to prevent improper or excessive loading, there is not a similar agreement respecting the means to be employed. For example some of the professional witnesses at the *Austral* inquiry expressed doubts as to the wisdom of placing in the hands of merchant-ship captains the results of calculations for stability expressed in the forms of "metacentric diagrams" or "curves of stability." These gentlemen feared that to the average ship-captain such curves and diagrams would be unintelligible, and therefore of no practical value. It must be admitted that there is some force in this contention; but on the other hand it is obvious that a very moderate amount of instruction ought to suffice to make information of the kind intelligible and useful to an educated seaman.

It may be worth while to mention what is the established practice in the Royal Navy in this matter. Each of Her Majesty's ships is provided with a "Statement of Stability," in which appears a record of the "metacentric heights," corresponding respectively to the "fully laden" and the "extreme light" conditions of the vessel. There is also a record of the calculations of stability at various angles of heel; the angle at which the stability attains its maximum and that at which it vanishes being noted. In cases where special precautions are needed special standing orders are given. For instance, in some low freeboard ships it is stringently ordered that a certain maximum load draught shall not be exceeded, because any diminution of the corresponding freeboard would cause an objectionable decrease in the range and area of the curve of stability. Again, in some vessels, as coals and stores are consumed, the stability is considerably diminished, and then orders are given that the ship shall not be lightened beyond a certain minimum draught, that draught being maintained if necessary by the admission of water-ballast. All these regulations are based upon careful experiment and detailed calculations. In the original design of the ships close attention is bestowed upon the question of their sufficient stability; and when the vessels are completed, an experimental check is put upon the intentions of the design, any necessary corrections being made in the original calculations. But it is right to remark that war ships are much more easily dealt with than merchant ships, because definite positions are assigned in them by the designer for all the weights carried—whether they be armour, or guns, or coals, or ammunition, or outfit. Hence it is possible to state distinctly what is the stability in the fully laden condition, and what are the extremes of possible variations in stability as coals, stores, &c., are consumed. In merchant ships, as was remarked above, the designer and builder have no corresponding control over stowage, and in practice very considerable variations in stowage necessarily occur. Leaving this difference aside for an instant, it may be stated that in the Royal Navy the information given on "Statements of Stability" is highly valued and well understood by naval officers. This result is, no doubt, attributable in a large degree to the fact that at the Royal Naval College for many years past classes have been arranged wherein naval officers receive instruction in the elements of naval architecture, and especially in the methods of interpreting the various statements and drawings issued by the Admiralty to the ships of the fleet. Similar instruction could not fail to be of service to officers of the mercantile marine, and the Admiralty have made provision in the Regulations for the admission of a certain number of such officers annually; but as yet no advantage has been taken of the permission. Either in this way or in some other, instruction must be obtained by merchant captains if they are to exercise an intelligent control over the loading of their vessels, and to insure the provision of sufficient stability.

It seems very probable that one result of recent occurrences and discussions will be the grant of greater freedom to shipbuilders in choosing the dimensions for new ships than has been customary hitherto. And it may be anticipated that increasing attention will be bestowed upon investigations of stability in connection with new designs. But whatever improvements may be made in the general practice of shipbuilders, the responsibility for management and loading must always remain with the owners and commanding officers of merchant ships. Ill-advised action on their part might render futile all the precautions of the designer. He may have secured what seems a good margin of stability, on the basis of some hypothetical arrangement of a certain dead weight which was supposed to be the maximum a ship would carry; and yet in practice some more critical condition of loading may arise which must be dealt with by those in charge of the vessel.

Having regard to the very considerable variations in the character of the cargoes carried by the great majority of merchant ships on their several voyages, it appears to be highly important that owners and captains should have placed in their possession full information respecting the stability of their ships; and that they should be able to make intelligent use of this information. One of the most valuable pieces of information which a captain could obtain for a laden ship would be her "metacentric height," and there seems no reason why an intelligent officer who had been furnished with a "metacentric diagram," and understood its use, should not experimentally determine for himself before leaving port what measure of "stiffness" his ship possessed, and at what vertical position the centre of gravity was placed (if the conditions of loading were of an unusual character). He would then have a more certain assurance of the sufficiency or otherwise of the stability of the ship than he could otherwise possess; and this assurance might easily be made to extend not merely to the initial stability but to the stability at large angles of inclination. It may be urged that it is too much to hope for any such experiments, or for such an advance in knowledge; and that in the stress of business time cannot be found for such elaborate inquiries. Possibly one may be too sanguine to indulge this hope; but inclining experiments of the kind indicated are neither lengthy nor costly operations, and their value as indications of the probable safety or danger of laden ships cannot well be over-estimated.

The necessity for carefully considering the stability of merchant ships is not a matter of dispute. All concerned may be assumed to desire some practical solution of the problems involved in securing sufficient stability. And on a review of the whole subject it will probably be admitted that all three classes interested—the shipowner, shipbuilder, and ship-captain—must accept their several responsibilities while working towards a common end. The shipowner may be presumed to know best the special requirements to be fulfilled in any new design. It is the duty of the designer to make sure that appropriate dimensions and proportions are secured in association with the fulfilment of these requirements, or to point out the impossibilty of such an association. And, finally upon the skilful and intelligent conduct of the captain must necessarily depend in a great degree the safety and success of the vessel during her career. In order that the best results may be obtained in face of the difficulties incidental to the design and management of many modern types of ships, the standard of knowledge must be raised in all three classes. W. H. WHITE

THE "ENCYCLOPÆDIA BRITANNICA"

Encyclopædia Britannica. Ninth Edition. Vol. xv. Loo-Mem. Vol. xvi. Men-Mos. (Edinburgh: A. and C. Black, 1883.)

AMONG the most important scientific articles in vol. xv. of the new edition of the "Britannica" are those on Medicine, Mechanics, and Mammalia.

The concise but comprehensive epitome of the history of medicine which Dr. Payne has contributed is the only history of the kind in the language. In Germany there are in this subject, as in almost every other branch of learning, excellent text-books; and the author acknowledges his obligations to Häser's "Lehrbuch der Geschichte der Medicin und der epidemischen Krankheiten." In France, Daremberg's "Histoire des Sciences Médicales" is also well known. But in England there has been no serious attempt to write a history of medicine since the publication of Freind's letters to Mead (1725); even these only dealt with a portion of the subject, and were written or at least begun under the disadvantage of confinement in the Tower. There have been a few valuable contributions to the subject, such as Dr. Greenhill's articles in Smith's "Dictionary of Classical Biography," and Dr. Munk's Roll of the College of Physicians, but nothing more.[1]

Is this neglect justifiable? In other branches of natural history and natural philosophy an acquaintance with the successive steps by which modern knowledge has been won is almost necessary for clearly comprehending the result. A history of astronomy, of electricity, or of physiology would be not only of interest but of practical value to the student of each of these subjects. But a history of medicine, however important as a chapter in the development of human intellect and the progress of civilisation, is scarcely any help towards understanding either the principles or the practice of the art of healing. A modern physician finds some knowledge of chemistry and of physics indispensable; botany and zoology are not without important bearing on his professional studies; a knowledge of German is of great practical use; but he may be ignorant of all medical literature above fifty years old without any loss, except the loss of the intellectual pleasure which every educated man should take in the past history of his profession.

That this is the case seems evident from the utter neglect of the older medical classics in medical education, notwithstanding occasional murmurs from the few who have earned the right to murmur by having read them, and from others—a neglect which exists not only in practical England and America, but no less in the learned German and the conservative French schools. This neglect is only confirmed by occasional glimpses of the said classics, and it is illustrated by the fact that we owe even the sketch of the labours of two thousand years which forms the subject of this review to the demands of an encyclopædia.

Nor is the reason far to seek. Modern medicine has scarcely anything but its aim in common with the art of the ancients. The attempt of the older physicians was to find some comprehensive explanation which would account for all the diseases of mankind, and their practical method was the application of certain remedies, recommended by the crudest experience, or more often by some such dogmatic criterion as that of "signatures." The authority of the ancients was regarded as independent of proof. In like manner naturalists used to study the worthless gossip of Pliny, and Milton recommended Columella as a school-book because of the practical importance of husbandry; indeed in England we still teach geometry from an ancient Greek text-book, and Euclid will be the last to follow Aristotle and Galen, Dioscorides and Celsus, into learned oblivion. But the object of modern medicine is not to explain but to investigate, to ascertain what is amiss, and to deal with it as directly as possible, on the principles of physics and of chemistry, guided by experiment and checked by skilled statistics. Homœopathy is only the last of the "systems" of medicine; not more arbitrary than many others, and, like the rest, not so much a wrong solution of a scientific problem as an answer to a question which cannot reasonably be put.

The art of rational medicine must therefore depend upon a knowledge of the body and its functions, on the power of discovering its physical conditions, and on acquaintance with the physico-chemical laws to which it is subject; just as the art of navigation depends on a knowledge of astronomy and of meteorology. But even the rough outlines of anatomy were only made out during the sixteenth and seventeenth centuries, and the discovery of its minuter details, so well begun between 1650 and 1700, was only resumed and carried to its present degree of completion by the achromatic microscopes of the last fifty years. Morbid anatomy dates from Morgagni. Physiology had no true existence before Harvey's discovery of the muscular contraction of the heart and the circulation of the blood in 1628. It was retarded rather than helped by premature application of mechanical laws, and did not make important progress again until the birth of chemistry in the last thirty years of the eighteenth century. If anatomy may be dated from the dissections of Vesalius, physiology from the vivisections of Harvey, and chemistry from the laboratory of Lavoisier, we cannot fix the beginning of modern medicine earlier than the introduction of mediate auscultation by Laennec in 1819.

Interest, however, will always belong to the history of medicine, apart from the practical value of the older medical literature. The study of the dreary succession of the Greek "sects," of the Galenical and Arabian "schools," and of the subsequent iatro-chemical, iatro-mechanical, Brunonian, and other "systems," is of service to warn too eager speculation from the errors of past ages. Here and there, "apparent rari, nantes in gurgite vasto," records of real observation: the aphorisms of Hippocrates, or the clinical pictures of Sydenham. Occasionally a good style commends an almost valueless treatise, as in the case of Celsus and Fracastori. More often we are attracted by some amusing gossip, some shrewd remark, or some interesting historical allusion, to epidemics or to wars, to the deaths of kings and conquerors, or to the daily accidents of contemporary life. Such are Caius's account of the sweating sickness, Ambrose Paré's description of his treatment of gunshot wounds in Savoy and at Rouen, and the "cases" recorded by Dutch surgeons of the seventeenth century. Nay, apart from utility and from such chance rewards as these, there will always be those who take the genuine delight of a book-worm in old authors because they are old, those who have the respectable appetite for information which is omnivorous, and students of the human mind for whom acquaintance with its dullest wanderings is fruitful.

---

[1] Dr. Edward Meryon's "History of Medicine" was never finished. Dr. Adams's editions of Hippocrates and of Paulus Ægineta, Croke's of the "Regimen Sanitatis Salernitanum," and Payne's of Linacre's translation, "De Temperamentis," are scholarly works. "Lives of British Physicians" and "The Gold-headed Cane" are not ungracefully written. "The History and Heroes of the Art of Medicine" is a very poor compilation. A brilliant essay on the subject will be found at the end of "Poems" and other remains of the late Dr. Frank Smith (Smith and Elder, 1879).

It is therefore well that English readers should have at least an outline of medicine in the past, and this want has been admirably supplied by Dr. Payne. Wisely abandoning all endeavours to include the biographical part of his subject, tempting as the excursion must often have seemed, and leaving on one side the curious history of medicine as a profession, its connection with the Church, the differentiation of its several branches, its varied social position, and the growth and decay of the great colleges and schools of medicine, he has aimed only at presenting within the narrow limits allowed (about thirty-seven columns quarto) a view of the changes of medical theories, and of the slow progress and frequent retrogression of the medical art. Beginning with an appreciative sketch of Hippocratic medicine, the important work of the Alexandrine physicians is next indicated, the scientific scope and character of Galen is described, and the obscure line of tradition of classical medicine is traced down to the mediæval school of Salerno. The vast, but thankless and little explored, field of Arabian medicine is then rapidly surveyed, and its dominion in Western Europe explained as being really little more than that of a corrupt Galenism. The revival of learning at the beginning of the sixteenth century was probably a misfortune to medicine, for when the Italian scholars, and our own Linacre and Caius translated the works of Galen into good Latin, these medical "classics" shared in the glory which surrounded the language of the New Testament and of Plato. The first steps of anatomy were in contradiction of statements by Galen, the first discovery of physiology was a refutation of his whole system. Yet the baneful influence of his great name, like that of the still greater name of Aristotle, lasted long after his claim to implicit credence had been disproved. As the ancient system was worn away, its place was eagerly striven for by the feebler systems of Paracelsus, Van Helmont, Borelli, Sylvius, Stahl, Hoffmann, John Brown, and Hahnemann in a long succession of three hundred years.

With the morbid anatomy of Morgagni, Baillie, and Laennec, and the physical diagnosis introduced by the latter great physician, the modern era of rational medicine began, in which sects and systems are mere survivals —superstitions—of an unduly prolonged middle age. At this point Dr. Payne's heart and paper seem to fail together. He ends, much as Gray's bard ended his prophetic outline of English history, in a fine confused view of a period of light and splendour, illustrated by the names of Rokitansky and Virchow, Czermak and Helmholtz, Bright, Graves, Addison, Stokes, and Trousseau. It was no doubt wise not to attempt an account of the triumphs of the new era, but we hope that the learned author of this article may make it the foundation of a complete history of medicine, fuller and more exact than Daremberg's, lighter and brighter than those of Sprengel and Häser. We also venture to suggest to the editor of the "Encyclopædia Britannica" that an article dealing with the curious and interesting history of medicine as a profession should be obtained from the same pen, under the heading, say, of "Physic, History of the Practitioners of."

We have scarcely left room for finding fault, and little room is needed. But to redeem our encomium from the charge of blindness, we may ask why the history of the school of Salerno is given after that of Arabian medicine; what evidence there is apart from his name that Bernard Gordon of Montpellier (1307) was a Scot; and what possible aptitude there is in a comparison between two such different persons as the impudent, drunken vagabond who called himself Paracelsus and the great German reformer who lived at the same time.

Lastly, while we fully admit the justice of connecting the introduction of auscultation and of chemical and microscopical examination of morbid fluids with the introduction of a knowledge of morbid anatomy—for this connection was, in fact, the *novum organum* of medicine from 1820 onwards—yet we think that there should also have been indicated, however briefly, the still newer method which has characterised the history of yet more recent medicine, namely, the method of number and measurement, by which to the stethoscope and the test tube have been added the clinical thermometer, the compte-globule and the sphygmograph. Perhaps future historians of medicine (particularly if they should write "primers" or "outlines" "for examination purposes") will divide the nineteenth century into four periods: the first (1800-1820) introductory, the second (1820-1850) the period of morbid anatomy and of physical diagnosis, the third (1850-1880) the period of morbid histology and of quantitative investigation; while the last, we may hope, will be called the period of experimental medicine, in which laboratories shall do the same service for pathology and therapeutics which they have already done for physiology.

There appears, under the head of "Mechanics," another of those mathematical dissertations which, each complete in itself, are to be found at such frequent intervals in the volumes of the new edition of the "Britannica." The author of the part of this article which treats of theoretical mechanics is Prof. Tait, and those who are familiar with his writings will be able to form an estimate of the way in which the treatment of the subject is conceived and carried out.

The science of mechanics in its widest range rests on Newton's Three Laws of Motion, and on that other passage in the "Principia" dealing with the activity of an agent, the full significance of which, when interpreted by the light of modern discoveries, was first made clear by Professors Thomson and Tait. An examination of Newton's original statement shows that in his view "equilibrium is not a balancing of forces, but a balancing of the effects of forces. When a mass rests on a table, gravity produces in it a vertically downward velocity which is continually neutralised by the equal upward velocity produced by the reaction of the table, and these forces . . . are equal because they produce in equal times equal and opposite quantities of motion."

As regards our knowledge of force as distinguished from its mechanical measure as change of momentum, we are reminded that our idea of force, originally derived from the muscular sense, "may be a mere suggestion of sense corresponding (no doubt) to some process going on outside us, but quite as different from the sensation which suggests it, as is a periodic shearing of the ether from brightness, or a periodic change of density of air from noise."

In discussing still further the nature of force, Prof. Tait points out that our belief in matter, the most certain of all objective realities, is largely based on the property of the unchangeability of its aggregate amount. "The only other thing in the universe which is conserved as matter is conserved is energy. Hence we conclude that energy is the true physical reality, and force, which is merely the space-rate at which energy is transformed, must be regarded like other expressions, such as rate of interest, death-rate, gradient of heat, as an expression introduced for convenience, and not necessarily because of an objective reality attached to it."

Remembering the dual nature of all force as being exerted between two bodies, we have, as another reading of the Third Law, "Every action between two bodies is a stress."

With regard to potential energy, which must depend in some hitherto unexplained way, like kinetic energy, on motion, Prof. Tait says: "The conclusion which appears inevitable is that, whatever matter may be, the other physical reality in the universe which is never found unassociated with matter, depends, in all its widely varied forms, upon motion of matter."

After explaining Newton's Laws, the author deals with the principles of kinematics, and then with statics and kinematics of various material systems, with different degrees of freedom, inserting amongst the analytical proofs several of those elegant geometrical constructions for which he is so well known. Whilst the nature of the article precludes a thorough exposition of the higher and more involved parts of the subject, he has succeeded in presenting illustrative problems of all the great divisions in mechanics, which afford some insight into the nature of the special parts of the subject to which they refer.

This most useful article, which exhibits the state of knowledge in theoretical mechanics at the present time, concludes with a list of the principal works on mechanics.

Following Prof. Tait's article, and under the heading of "Applied Mechanics," we have the reprint of an article by the late Prof. Rankine, contributed by him to the volume of the "Encyclopædia Britannica" which was published in 1857.

In this article Prof. Rankine has dealt with the principles of the subject very much on the same lines as in his larger published work on "Applied Mechanics." It is needless to say that nothing that Rankine wrote on the theory of mechanics can ever become antiquated or obsolete. He possessed such a firm grasp of the foundations of the subject, that it seems impossible to believe that on these points he could commit an error. But since that time many new discoveries have been made in mechanics, as in other sciences, to which we find no reference in the present articles. Of these perhaps the most important are the later developments of graphical statics, and the kinematical analysis of Prof. Reuleaux. The former subject, which really dates its origin from the time of the discoveries by Rankine of the Theory of the Extension of the Funicular Polygon, and by Clerk Maxwell of the Theory of Reciprocal Figures, has received at the hands of Culmann and others developments which are now proving themselves of the greatest importance in engineering design. Of the higher parts of these more modern methods no information is given, either in the article before us, or in the extremely clear and simple theory of Frames, which appears in Prof. Jenkin's article on "Bridges," in the fourth volume of this "Encyclopædia," or in any other place in the work, and having regard to the importance of the subject, we cannot but regret its absence.

We believe that had the work of Reuleaux been published earlier, Rankine would have been one of the first to recognise its beauty and value.

The whole article displays the power of logical arrangement and method, as well as the condensed style which is so characteristic of all Rankine's writings, and makes them such difficult reading for beginners. These will probably prefer his "Applied Mechanics," for purposes of study, to the article before us. But as an exposition, in small compass, of the leading principles of that science, it is altogether admirable as far as it goes, whilst its value is increased by the numerous articles in this "Encyclopædia" on special, more technical parts of the subject, such as that of Prof. Jenkin, already quoted, and that of Prof. Unwin on "Hydraulics," and others which are promised in forthcoming volumes.

The article on "Mammalia," by Prof. Flower, is an extremely well condensed and intelligibly written essay on the highest class of vertebrate beings, for which, as the author notes, there has never been a generally accepted vernacular designation. Still the class known to zoologists as Mammals is one rigidly defined, and one that obeys the strictest rules of logic in its definition, despite Kant's remarks on the impossibility of defining strictly natural objects. It is easy to imagine the mammary glands reduced to a state of extreme simplicity, but among living mammals this never occurs, nor is there any gland to be confounded with them in any other vertebrate form. The article opens with a chapter on the general anatomical characters of the class, in which an immense amount of accurate information is compressed into a small space. Many of the figures illustrating the details of the osteology are taken from Prof. Flower's well-known work on this subject. In the chapter on classification, the recent arguments of Prof. Huxley in favour of passing over all known forms of birds and reptiles and going straight to the amphibia for the progenitors of the mammalia are quoted with approval; and that author's subdivision of the class into three sub-branches—Prototheria, Metatheria, and Eutheria—is adopted. The history of the distribution of the mammals in time and space follows; and then we have the characters of the different orders and families, and of the principal forms of the class. In this section of the memoir the illustrations, taken from the best sources, are especially to be praised, and in many instances the information as to rare or new species is brought well up to date. This seems to us especially so in the interesting group of the bats and insectivora, for which Prof. Flower acknowledges his indebtedness to Dr. G. E. Dobson, but in the portion devoted to the order Primates, an order which Prof. Flower makes to include the lemurs, the monkeys, and man, we read the little that is written under the impression that it was but introductory to a good deal that was to follow, and when we turned over to p. 446 we found the essay was finished and that we had arrived at the index; even this bears marks of a forced compression, for while the earlier letters are fairly done, the last in the index have evidently had a lot "squeezed" out.

One other article relating to zoology in this volume is also by Prof. W. H. Flower, on the "Mammoth." He alludes to the derivation of this name as being by some ascribed to a Tartar origin, by others that it is a corruption of the Arabic word *Behemoth*, or great beast, but on the authority of Prof. Sayce it is a corruption of the Biblical Behemoth, Arabic behîmat.

The scientific articles in vol. xvi. are so numerous and important that it is impossible for us to give them satisfactory notice in the space at our disposal; we can do no more than name the more important. From Prof. Dittmar we have Metallurgy and Metals; Prof. Chandler Roberts and Mr. R. A. Hill contribute the article on Mint, in which all aspects of the subject are fully as well as interestingly treated; while Mining, by Dr. Le Neve Foster, is both practical and scientific. Meteorology, of course, has been undertaken by Mr. Buchan and Prof. Balfour Stewart, and forms an admirable exposition of the present condition of a science of great and growing complexity; Mr. Buchan treating of instruments and phenomena, while Prof. Stewart deals with the science that underlies the subject. The article on Micrometer is by Dr. David Gill; while it is natural to find Dr. W. B. Carpenter's name attached to that on Microscope. Prof. Heddle contributes an elaborate and profusely illustrated article on Mineralogy. Molecule has a triple authorship, Rev. H. W. Watson, Mr. S. H. Burbury, and Prof. Crum Brown, both its physical and chemical aspects being thus fully treated. The article on Mollusca in this volume, by Prof. Ray Lankester, is as complete and masterly and richly illustrated as that on Mammalia in the previous volume. Under Moon we have a short article on the lunar theory, by Prof. Simon Newcomb; other aspects of the subject have been dealt with under Astronomy. Mr. P. Geddes has a careful and wonderfully exhaustive article on Morphology; and Mr. R. M'Lachlan finishes off the volume with a somewhat tiny article on Mosquito. There are many other smaller articles in all departments of science,—Prof. A. Newton, for example, doing all birds,—and several important ethnologico-geographical articles, as Mexico, by Mr. E. B. Tylor and Prof. Keane, and Mongols, by Prof. Douglas and Prof. Jülg. We hope in a future number to be able to refer in detail to some of the articles mentioned.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Living Scorpions, Mygale, and Protopterus

WILL you allow me to use your columns in order to ask any of your readers residing in tropical localities, who may be generous enough to wish to help a naturalist in his researches, to send to me *living* specimens of *large* Scorpions (not less than three inches in length), and *living* specimens of large Mygale (birdsnesting spider); also I would beg for *living* Earthworms of large size from African, Indian, American, and Australian localities. Any of these animals can be sent in a small tin box in which a few holes are perforated; the tin box being packed in a much larger wooden box with hay or loose paper. Damp moss should be placed with the Scorpion or Mygale. Each specimen should be inclosed in a separate tin box, since these animals are cannibals. The holes in the tin box containing an Earthworm should be very few, and the amount of damp moss very great. Earthworms would travel best in a Wardian case, should the opportunity offer—not loose, but in the above-mentioned tin box.

I would further take this opportunity to ask for information concerning the best way of keeping the African Lepidosiren, or mud-fish (*Protopterus annectens*), in confinement. I require to ascertain (1) its natural food, (2) the temperature of the waters in which it naturally lives, (3) whether these are stagnant or rapidly running, (4) whether anything is known as to habits in the breeding season, and if this season immediately precedes or succeeds the dry season.

Some of your readers in this country or in Africa may have gained experience on these points, and would greatly help me in an attempt to breed the mud-fish by communicating with me.

E. RAY LANKESTER

Electricity in India.—The Green Sun

[THE following letter has been sent us for publication by Sir William Thomson, to whom it is addressed:—]

For nearly a month the air has been in a state of electrification, which seems to me so interesting that I thought you would probably like to hear of it at once without my waiting to complete my observations. Unfortunately I cannot tell the exact date at which it began, but August 31 showed positive electricity all day apparently. On September 1 and 2, I was not able to get any measurements, but on the 3rd at 1.10 p.m., I got negative readings from −28 to −17 div., wind light, S. by W. By 2.45 it had changed to +6. Next morning at 10.5 a.m. it varied from −136 to −44; this was on the roof. I then took it to the ground, to a place quite open, and found readings from −460 in gusts of wind to −162 when the wind was light. The wind was fresh, westerly. Up to 1h. 14m. it continued negative, but at my next reading, 3 p.m., it was +35, and remained steadily positive, the wind having now gone round to the east (sea breeze).

5th, 6 a.m., positive, from 9 a.m. to 2.5 negative, and thereafter positive.

This continued with the exception of the 9th, when it was positive all day till the 13th.

On the 20th the reading at 9.55 was −34, but at 11.55 it was +44, the wind in the meanwhile having changed from west (land wind) to east (sea breeze). A similar state of affairs still continues.

During all this time the weather in Madras has been fine, and for some days at first, when I made very special inquiries, I found that no rain had fallen within 100 miles of Madras. It may perhaps be worth mentioning that from the 8th to the 14th we have had the strange phenomenon of a bright green sun at sunrise and sunset, the sun appearing as a rayless globe, at which you could easily look, and yet so sharply defined that sunspots could be well seen with the naked eye. On the 22nd again, two days after the electricity had gone to positive, the green sun reappeared, and has now changed to a sort of golden green. I do not say that there is any connection between the two, but they seem worth mentioning together. I have got a large number of observations which I will reduce as soon as possible, and send to the Royal Society of Edinburgh, but there is no use doing this till things return to their normal state. It is worth pointing out that observations made at intervals of six hours might have entirely failed to find the negative electricity. I usually, for convenience, take observations at 9 a.m., before leaving for college, and the next would be at three, and both these are always positive. I have not got the exact scale of my electrometer, but I find that 100 Daniell's cells give only 24 div. of a deflection. I am very much disappointed that I have not got my new instrument yet. Had I had it I would have been able to get simultaneous observations carried on at Madras and at a place forty miles to the west, which might have given valuable results. My present instrument, though working better than before, needs constant recharging. For example, at noon yesterday the earth reading was 1750, and at six this morning it was only 1440. C. Michie Smith

Christian College, Madras, September 26

Unusual Cloud-Glow after Sunset

Yesterday evening a most extraordinary sunset effect was seen here, which made a deep impression on all who observed it. The sky was nearly clear when the sun set at 4.18, and the air transparent. A few cirrocumulus fleeces became lighted up with a pink and then with a deep red colour immediately after sunset. A very peculiar greenish and white opalescent haze now appeared about the point of the sun's departure, and shone as if with a light of its own, near the horizon. The upper part of this pearly mist soon assumed a pink colour, while the lower part was white, green, and greenish-yellow. About 4.35 the sky from near the horizon towards the zenith had begun to turn to a brilliant but delicate pink, and some pink cirrus-like streaks stretched apparently horizontally towards the south-east. The coloured portion of the sky spread out like a sheaf from the horizon, and apparently consisted of a very high, thin filmy cirrus disposed in transverse bands or ripples, close together, and very delicate in form, outline, and tint. Below the pink, and between it and the point where the sun had set, remained the very curious, opalescent, shining, green and white vapour, hanging, as it were, vertically, and changing very little during many minutes. The borders of the pink sheaf were definite, and finely contrasted with the deep blue sky. As darkness came on, the pink glow seemed to increase in brightness, and at five o'clock cast a fine weird light over the hills. The moon was now bright in the south-east, and began to cast dark shadows. About five the colour slowly receded from the part nearest the zenith towards the horizon, and as it retired left a clearly visible filmy ripple of cirrus of a faint gray tint. At 5.25 the greater part of the colour was gone, and the cloud remained bright only near the horizon. At 5.32, however, it began to grow again, and in a short time (5.40) the whole extent of the film was again glowing bright pink, producing a most striking effect in contrast with the silvery moon, dark sky, and bright stars in the north and east. The pink light then slowly withdrew towards the horizon, remaining bright and deep coloured low down till 5.50. At 5.58 the last pink disappeared. The whole phenomenon from first to last was in the highest degree peculiar and striking. It was remarkable, first, for the interval which elapsed between the time of sunset and the time at which the cloud became bright, next for the light, filmy character of the cloud, thirdly for the bright green glow near the place of sunset, fourthly for the small transverse ripple form of the cloud, fifthly for the permanence of shape and immobility of the cloud, sixthly for the very long endurance of the coloured reflected sunlight after sunset, one hour and forty minutes, and seventhly for the second illumination, which began more than an hour after sunset. It was certainly due to cirrus or a higher kind of cloud, because (1) parts of the illuminated sky stretched in long streaks southwards, and the glow remained long in these streaks, resembling very high cirrus; (2) when the light left the sky the first time, the part which had been illuminated remained visible as silvery gray cloud ripples, before the second after-glow rekindled it, and (3) because the colour became very gradually darker as time went on, and because the recessions of light both times were towards the place of sunset. A similar very high cirrus had also been specially marked long after sunset on November 8, and about the time of sunrise on November 9. The night following this rare display was exceedingly clear and fine. This evening (November 10) the light, high cirrus, all but invisible in full daylight, with its delicate ripples, assumed the pink tint about fifteen minutes after sunset, showing the upper air to be in the same abnormal condition as yesterday, and the phenomenon was feebly repeated. It would be interesting to ascertain the approximate height of cirrus on which sunshine remains one hour and forty minutes after sunset at this time of year. F. A. R. Russell

Dunrozel, Haslemere, Surrey, November 10

Shadow-Beams in the East at Sunset

The phenomenon of beams of shadow meeting in the east at sunset, treated of in the pages of Nature some months since (at which time you did me the honour of inserting a letter of mine), was beautifully witnessed here to-day and yesterday. Both days were unusually clear; there was, nevertheless, a "body" in the air, without which the propagation of the beams could not take place. Yesterday the sky was striped with cirrus cloud like the swaths of a hayfield; only in the east there was a bay or reach of clear blue sky, and in this the shadow-beams appeared, slender, colourless, and radiating every way like a fan wide open. This lasted from 3.30 to about 4.30. To-day the sky was cloudless, except for a low bank in the west; in the east was a "cast" of blue mist, from which sprang alternate broad bands of rose colour and blue, slightly fringed. I was not able to look for them till about 4.30, when the sun was down, and they soon faded. I have not before seen this appearance so far north, but on the south coast, where I first saw it, I think it might often be witnessed. It is merely an effect of perspective, but a strange and beautiful one.

Stonyhurst College, November 12 Gerard Hopkins

The Java Eruption

The accompanying paragraph may be of interest in connection with the Java catastrophe. I may mention that from the 28th of last month, when I first noticed it, there has been an exceptional red glow after sundown, and a strange green tint in the sky, while till the last few days the moon has had a distinctly green tint; this green tint has been noticed in many parts of India. F. C. Constable

Karachi, October 16

A Floating Lava Bed.—Sir,—It may be interesting to some of your scientific readers to know that the steamship *Siam*, on her voyage from King George's Sound to Colombo, on August 1, when in lat. 6° S., 89° E., passed, for upwards of four hours, through large quantities of lava, which extended as far as could be seen (the ship was going eleven knots at the time). The lava was floating in a succession of lanes from five to ten yards wide, and trending in a direction north-west to south-east. The nearest land was the coast of Sumatra (distant 700 miles), but as there was a current of fifteen to thirty miles a day, setting to the eastward, the lava could not have come from there, and I can only imagine it must have been an upheaval from somewhere near the spot. I may mention the soundings on the chart show over 2,000 fathoms. There was a submarine volcano near the spot in 1879.—Edward Ashdown, Commander, P. and O. steamship *Siam*. (*Sind Gazette Bulletin*, October 12.)

Towering of Birds

When shooting in Fifeshire last October I fired at a partridge at a distance of about forty yards; the bird flew on for a short distance, and then began to rise, not in the manner in which a towering bird generally ascends, but soaring as if it did so voluntarily. After rising to the height of 100 or 150 yards very much after the fashion in which some hawks soar, its flight was suddenly deflected downwards obliquely for a considerable distance, when it swerved, and came towards the ground in a different direction, alighting as though it were in possession of its natural powers, some hundreds of yards from the place whence it rose. On going to the spot where it had settled, it was found to be alive and crouching in the long grass. The keeper ran in and placed his hand on it, when the bird struggled and tried to get away; he killed it seeing that it was wounded. On examining the bird immediately after I found that it had been struck by two pellets of No. 6 shot, one of which had penetrated the pectoral muscles, but had not injured the cavity; the lungs and other viscera were uninjured. The other pellet had entered behind and below the left eyeball, and, passing forward, had emerged on the other side, passing above the upper mandible. The brain was uninjured, but the lower part of the left eyeball was cut and distended with blood. There was no other injury. No doubt the shock had confused the bird, and caused its strange flight, which, though upward, was very different in its character from that of ordinary towering where the lungs are perforated, and unconsciousness is the result of the circulation of non-aërated blood.

J. FAYRER

Meteors

PERMIT me to point out to Mr. J. M. Hayward (NATURE, Nov. 8, p. 30) that his observation of the large meteor of November 4 possesses no scientific value, inasmuch as he has omitted to mention the important features of its appearance. The time is given as "just now" (or November 4), and the broad path of fire which this fine meteor discharged upon its course must have been situated *somewhere* in the south-east, for your correspondent states he saw it "on turning to the south-east."

I had endeavoured to show in NATURE of the preceding week (Nov. 1, p. 6) that these delightfully vague forms of expression as applied to meteors are wholly inadequate, and, as such, cannot receive any attention at the hands of those who investigate these phenomena.

Had Mr. Hayward given us the essential details of his observation, it might have proved very valuable, for a large meteor (perhaps identical with the one he refers to) was observed at many places on the night of November 4. As recorded at Chelmsford, Bath, and Bristol the paths were:—

Time.		Mag.	From		To		Observer.
			α	δ	α	δ	
1883.	h. m.		°	°			
Nov. 4	10 14	= ♀	8	S. 20	355	S. 30	H. Corder, Chelmsford.
Nov. 4	10 12	6 × ♃	33	S. 6	9	S. 23	J. L. Stothert, Bath.
Nov. 4	10 12	> ♃	36	N. 1½	16	S. 19	W. F. Denning, Bristol.

The several estimates of brilliancy are very discordant, but the time and paths agree so closely that there is little doubt the observations refer to the same meteor.

Another fine meteor was seen here on October 26 at 9h. 17m. It gave a succession of four lightning-like flashes. Path from α 288 δ 56° + to α 333° δ 59° +. This was not the only fireball visible that night, for I see by NATURE (November 8, p. 44) that "On October 26 at about 7 p.m. a splendid meteor was seen in the district of Hernösand, Sweden." It appeared "with a blinding white lustre in the zenith and travelling very rapidly down to the horizon." In this case again we have to deplore the extremely vague manner of the description. Had the precise direction of flight been given, it would have been interesting to determine whether this fireball belonged to the same stream as the equally fine one recorded at Bristol on the same night.

W. F. DENNING

Bristol, November 10

THE meteors during October have been numerous, and the most of them proceeded from some point in Auriga. With the exception of about nine days of unfavourable weather, I have seen several meteors night and morning throughout October, but they were generally small and transient. I have counted fifty-two from 10 p.m. of October 3 to 4·30 a.m. of the 4th, many of them large and of several seconds' duration. The largest of these passed slowly from the first bright star on the left of Capella, in Auriga, to a point about 1° below α Cygni. The smallest of them blinked rapidly before the eye in the zenith over the Milky Way, which, this night, was the principal theatre of their display. From 3.30 to 4.30 a.m. I counted forty of the fifty-two meteors. From 1 a.m. to 4 of October 8 I observed very brilliant meteors. One at 2.25 a.m. darted from about 1° above Capella and disappeared at a point ½° from Phad in the Plough, without exploding and without leaving any trace of light behind. It was as large as Venus. At 2.40 a.m. a very large and brilliant meteor dashed out from a point midway between Capella and the first bright star to its right in Auriga, and sped along above the Pleiades and Aries through the Square of Pegasus, and exploded 3° beyond it, leaving no fire in its wake. October 15, 11.38 p.m., a very unusual meteor sailed slowly from β Ceti to within 1° of Betelgueux, in the right shoulder of Orion. After travelling two-thirds of its journey, it exploded into four, three of which formed the head of an arrow, and the fourth adorned its tail, all the four sending out bright nebulous light behind them. At 2.50 a.m., October 26, a large ball of fire (bolide), apparently seven inches in diameter, illumined the heavens with great brilliancy as it descended from about midway between the third and fourth bright stars on the left of Capella, exploding twice during the last half of its journey, and disappearing just as it reached the moon. It had no tail. It was seen by some of the Paisley night police, and one of them was frightened that it would dash the moon out of the heavens. This bolide had no detonation in either of its two explosions, and the last of it was only about the size of Jupiter. One policeman describes it as a large fiery ball of the size of the full moon, but this is an exaggeration. The extraordinary meteor of October 15, after its explosion, was described by an observer as a well-formed arrow of flaming fire, followed by a ball of fire with a tail. To me it appeared to resemble the head and body of a fish, as well as the form of an arrow.

DONALD CAMERON

Mossvale, Paisley, November 6

ON the evening of Saturday last, at 10.12 p.m., a remarkable meteorite was observed close to Trinity College, Glenalmond, in Perthshire. It presented the appearance of a bright spherical ball, which moved horizontally from east-north-east to west-south-west at a height roughly estimated at 300 feet. When it began to curve downwards it disappeared from view, but it left behind it a luminous trail of great brilliancy, which was seen for fully forty seconds, its brilliancy gradually diminishing till it entirely faded away.

W. BESANT LOWE

Trinity College, Glenalmond, Perth, November 12

"Anatomy for Artists"

I AM quite unable to do as your correspondent "An Art Student" suggests, for the second edition of the above-named book has been just issued. I may add, however, that the reasons which led me deliberately to adopt the plan alluded to in regard to the illustrations of the bones still remain, in my opinion, sound, and I trust that the majority of my readers of the past, present, and future editions have not been and will not be "discouraged" by the effort which I desire them, for their own sakes as students, to make.

JOHN MARSHALL

10, Savile Row, W., November 12

P.S.—It seems that *I* ought to have two "letters of reference" attached to myself, for I am not "Dr." but "Mr." Marshall.

Earthquake

NATURE on October 25 contained notices of shocks of earthquake which were felt at a quarter to one o'clock on the night of October 19 (11h. 20m. Greenwich M.T.) at Cadiz and other places on the coast of Andalusia. I have information that about 17h. 45m. later these shocks, which were travelling from east to west, had apparently reached Bermudas. In a letter just received from ex-Chief Justice Darrell, dated October 22, he remarks:—"A very unusual event occurred here on the 20th of this month, in a shock of an earthquake, which however was slight; no life was lost, nor serious damage done to buildings; but the shock, which lasted less than a minute, at about a quarter past one p.m. was universally and unmistakably felt throughout the colony. It is said to be only the third time that any earthquake has been experienced in Bermuda in the last forty years." A quarter past one in Bermuda would be about four and a half minutes past five at Greenwich, requiring, if the shocks originated in the same wave, a rate of transmission of about 158 geographical miles an hour, or 2·6 miles per minute; less than half the rate at which the great shocks of 1755 and 1761 crossed the Atlantic from Lisbon to Barbados, which is given by Mallet as 7·3 miles, or 6·3 geographical miles per minute.[1]

J. H. Lefroy

"Partials"

In your number of Nov. 1, p. 6, I noticed an article the object of which was to account for the existence of "partials." Were the theory therein set forth correct, we should have a constant number of "partials" for any given "fundamental" tone of constant force regardless of its source; whereas it is a well-known fact that, while the tones of some instruments are rich in "partials," those of other instruments have but few.

SCIENCE AND ENGINEERING

In the address delivered by Mr. Westmacott, President of the Institution of Mechanical Engineers, to the English and Belgian engineers assembled at Liége last August, there occurred the following passage:—"Engineering brings all other sciences into play: chemical or physical discoveries, such as those of Faraday, would be of little practical use if engineers were not ready with mechanical appliances to carry them out, and make them commercially successful in the way best suited to each."

We have no objection to make to these words, spoken at such a time and before such an assembly. It would of course be easy to take the converse view, and observe that engineering would have made little progress in modern times, but for the splendid resources which the discoveries of pure science have placed at her disposal, and which she has only had to adopt and utilise for her own purposes. But there is no need to quarrel over two opposite modes of stating the same fact. There *is* need on the other hand that the fact itself should be fairly recognised and accepted, namely, that science may be looked upon as at once the handmaid and the guide of art, art as at once the pupil and the supporter of science. In the present article we propose to give a few illustrations which will bring out and emphasise this truth.

We could scarcely find a better instance than is furnished to our hand in the sentence we have chosen for a text. No man ever worked with a more single-hearted devotion to pure science—with a more absolute disregard of money or fame, as compared with knowledge—than Michael Faraday. Yet future ages will perhaps judge that no stronger impulse was ever given to the progress of industrial art, or to the advancement of the material interests of mankind, than the impulse which sprang from his discoveries in electricity and magnetism. Of these discoveries we are only now beginning to reap the benefit. But we have merely to consider the position which the dynamo-electric machine already occupies in the industrial world, and the far higher position which, as almost all admit, it is destined to occupy in the future, in order to see how much we owe to Faraday's establishment of the connection between magnetism and electricity. That is one side of the question—the debt which art owes to science. But let us look at the other side also. Does science owe nothing to art? Will any one say that we should know as much as we do concerning the theory of the dynamo-electric motor, and the laws of electro-magnetic action generally, if that motor had never risen (or fallen, as you choose to put it) to be something besides the instrument of a laboratory, or the toy of a lecture-room. Only a short time since the illustrious French physicist, M. Tresca, was enumerating the various sources of loss in the transmission of power by electricity along a fixed wire, as elucidated in the careful and elaborate experiments inaugurated by M. Marcel Deprez, and subsequently continued by himself. These losses—the electrical no less than the mechanical losses—are being thoroughly and minutely examined in the hope of reducing them to the lowest limit; and this examination cannot fail to throw much light on the exact distribution of the energy imparted to a dynamo machine, and the laws by which this distribution is governed. But would this examination ever have taken place—would the costly experiments which render it feasible ever have been performed—if the dynamo machine was still under the undisputed control of pure science, and had not become subject to the sway of the capitalist and the engineer?

Of course the electric telegraph affords an earlier and perhaps as good an illustration of the same fact. The discovery that electricity would pass along a wire and actuate a needle at the other end was at first a purely scientific one; and it was only gradually that its importance, from an industrial point of view, came to be recognised. Here again art owes to pure science the creation of a complete and important branch of engineering, whose works are spread like a net over the whole face of the globe. On the other hand, our knowledge of electricity, and specially of the electro-chemical processes which go on in the working of batteries, has been enormously improved in consequence of the use of such batteries for the purposes of telegraphy.

Let us turn to another example in a different branch of science. Whichever of our modern discoveries we may consider to be the most startling and important, there can I think be no doubt that the most beautiful is that of the spectroscope. It has enabled us to do that which but a few years before its introduction was taken for the very type of the impossible, viz. to study the chemical composition of the stars; and it is giving us clearer and clearer insight every day into the condition of the great luminary which forms the centre of our system. Still, however beautiful and interesting such results may be, it might well be thought that they could never have any practical application, and that the spectroscope at least would remain an instrument of science, but of science alone. This however is not the case. Some thirty years since Mr. Bessemer conceived the idea that the injurious constituents of raw iron—such as silicon, sulphur, &c.—might be got rid of by simple oxidation. The mass of crude metal was heated to a very high temperature; atmospheric air was forced through it at a considerable pressure; and the oxygen uniting with these metalloids carried them off in the form of acid gases. The very act of union generated a vast quantity of heat, which itself assisted the continuance of the process; and the gas therefore passed off in a highly luminous condition. But the important point was to know where to stop; to seize the exact moment when all or practically all hurtful ingredients had been removed, and before the oxygen had turned from them to attack the iron itself. How was this point to be ascertained? It was soon suggested that each of these gases in its incandescent state would show its own peculiar spectrum; and that, if the flame rushing out of the throat of the converter were viewed through a spectroscope, the moment when any substance such as sulphur had disappeared would be known by the disappearance of the corresponding lines in the spectrum. The anticipation, it is needless to say, was verified; and the spectroscope, though now superseded, had for a time its place among the regular appliances necessary for the carrying on of the Bessemer process.

This process itself, with all the momentous consequences, mechanical, commercial, and economical, which it has entailed, might be brought forward as a witness on our side; for it was almost completely worked out in the laboratory before being submitted to actual practice. In this respect it stands in marked contrast to the earlier processes for the making of iron and steel, which were developed, it is difficult to say how, in the forge or furnace itself, and amid the smoke and din of practical work. At the same time the experiments of Bessemer were for the most part carried out with a distinct eye to their future application in practice, and their value for our present purpose is therefore not so great. The same we believe may be said with regard to the great rival of the Bessemer converter, viz. the Siemens open hearth; although this forms in itself a beautiful application of the scientific doctrine that steel stands midway, as regards its proportion of carbon, between wrought iron and pig iron, and ought therefore to be obtainable by a judicious mixture of the two. The basic process is the latest development, in this direction, of science as applied to metallurgy. Here, by simply giving a different chemical constitution to the clay lining of the converter, it is found possible to eliminate phosphorus—an element which has successfully withstood the attack of the Bessemer system. Now, to quote the words of a German eulogiser of the new method, phosphorus has been turned from an enemy into a friend; and the richer a given ore is in that substance, the more readily and cheaply does it seem likely to be converted into steel.

---

[1] Mallet's Fourth Report, British Association, 1858.

These latter examples have been taken from the art of metallurgy; and it may of course be said that, considering the intimate relations between that art and the science of chemistry, there can be no wonder if the former is largely dependent for its progress on the latter. I will therefore turn to what may appear the most concrete, practical, and unscientific of all arts—that, namely, of the mechanical engineer; and we shall find that even here examples will not fail us of the boons which pure science has conferred upon the art of construction, nor even perhaps of the reciprocal advantages which she has derived from the connection.

The address of Mr. Westmacott, from which I have already taken my text, supplies in itself more than one instance of the kind we seek—instances emphasised by papers read at the meeting where the address was spoken. Let us take, first, the manufacture of sugar from beetroot. This manufacture was forced into prominence in the early years of this century, when the Continental blockade maintained by England against Napoleon prevented all importation of sugar from America; and it has now attained very large dimensions, as all frequenters of the Continent must be aware. The process, as exhaustively described by a Belgian engineer, M. Mélin, offers several instances of the application of chemical and physical science to practical purposes. Thus, the first operation in making sugar from beetroot is to separate the juice from the flesh, the former being as much as 95 per cent. of the whole weight. Formerly this was accomplished by rasping the roots into a pulp, and then pressing the pulp in powerful hydraulic presses; in other words, by purely mechanical means. This process is now to a large extent superseded by what is called the diffusion process, depending on the well known physical phenomena of *endosmosis* and *exosmosis*. The beetroot is cut up into small slices called "cossettes," and these are placed in vessels filled with water. The result is that a current of endosmosis takes place from the water towards the juice in the cells, and a current of exosmosis from the juice towards the water. These currents go on cell by cell, and continue until a state of equilibrium is attained. The richer the water and the poorer the juice, the sooner does this equilibrium take place. Consequently the vessels are arranged in a series, forming what is called a diffusion battery; the pure water is admitted to the first vessel, in which the slices have already been nearly exhausted, and subtracts from them what juice there is left. It then passes as a thin juice to the next vessel, in which the slices are richer, and the process begins again. In the last vessel the water which has already done its work in all the previous vessels comes into contact with fresh slices, and begins the operation upon them. The same process has been applied at the other end of the manufacture of sugar. After the juice has been purified, and all the crystallisable sugar has been separated from it by boiling, there is left a mass of molasses, containing so much of the salts of potassium and sodium that no further crystallisation of the yet remaining sugar is possible. The object of the process called osmosis is to carry off these salts. The apparatus used, or osmogene, consists of a series of trays filled alternately with molasses and water, the bottoms being formed of parchment paper. A current passes through this paper in each direction, part of the water entering the molasses, and part of the salts, together with a certain quantity of sugar, entering the water. The result of thus freeing the molasses from the salts is that a large part of the remaining sugar can now be extracted by crystallisation.

Another instance in point comes from a paper dealing with the question of the construction of long tunnels. In England this has been chiefly discussed of late in connection with the Channel Tunnel, where, however, the conditions are comparatively simple. It is of still greater importance abroad. Two tunnels have already been pierced through the Alps; a third is nearly completed; and a fourth, the Simplon Tunnel, which will be the longest of any, is at this moment the subject of a most active study on the part of French engineers. In America, especially in connection with the deep mines of the western States, the problem is also of the highest importance. But the driving of such tunnels would be financially if not physically impossible, but for the resources which science has placed in our hands, first, by the preparation of new explosives, and, secondly, by methods of dealing with the very high temperatures which have to be encountered. As regards the first, the history of explosives is scarcely anything else than a record of the application of chemical principles to practical purposes—a record which in great part has yet to be written, and on which we cannot here dwell. It is certain, however, that but for the invention of nitroglycerine, a purely chemical compound, and its development in various forms, more or less safe and convenient, these long tunnels would never have been constructed. As regards the second point, the question of temperature is really the most formidable with which the tunnel engineer has to contend. In the St. Gothard Tunnel, just before the meeting of the two headings in February, 1880, the temperature rose as high as 93° Fahr. This, combined with the foulness of the air, produced an immense diminution in the work done per person and per horse employed, whilst several men were actually killed by the dynamite gases, and others suffered from a disease which was traced to a hitherto unknown species of internal worm. If the Simplon Tunnel should be constructed, yet higher temperatures may probably have to be dealt with. Although science can hardly be said to have completely mastered these difficulties, much has been done in that direction. A great deal of mechanical work has of course to be carried on at the face or far end of such a heading, and there are various means by which it might be done. But by far the most satisfactory solution, in most cases at least, is obtained by taking advantage of the properties of compressed air. Air can be compressed at the end of the tunnel either by steam-engines, or, still better, by turbines where water power is available. This compressed air may easily be led in pipes to the face of the heading, and used there to drive the small engines which work the rock-drilling machines, &c. The efficiency of such machines is doubtless low, chiefly owing to the physical fact that the air is heated by compression, and that much of this heat is lost whilst it traverses the long line of pipes leading to the scene of action. But here we have a great advantage from the point of view of ventilation; for as the air gained heat while being compressed, so it loses heat while expanding; and the result is that a current of cold and fresh air is continually issuing from the machines at the face of the heading, just where it is most wanted. In consequence, in the St. Gothard, as just alluded to, the hottest parts were always some little distance behind the face of the heading. Although in this case as much as 120,000 cubic metres of air (taken at atmospheric pressure) were daily poured into the heading, yet the ventilation was very insufficient. Moreover, the high pressure which is used for working the machines is not the best adapted for ventilation; and in the Arlberg tunnel separate ventilating pipes are employed, containing air compressed to about one atmosphere, which is delivered in much larger quantities, although not at so low a temperature. In connection with this question of ventilation a long series of observations have been taken at the St. Gothard, both during and since the construction: these have revealed the important physical fact (itself of high practical importance) that the barometer never stands at the same level on the two sides of a great mountain chain; and so have made valuable contributions to the science of meteorology.

Another most important use of the same scientific fact, namely, the properties of compressed air, is found in the sinking of foundations below water. When the piers of a bridge, or other structure, had to be placed in a deep stream, the old method was to drive a double row of piles round the place and fill them in with clay, forming what is called a cofferdam. The water was pumped out from the interior, and the foundation laid in the open. This is always a very expensive process, and in rapid streams is scarcely practicable. In recent times large bottomless cases, called caissons, have been used, with tubes attached to the roof, by which air can be forced into or out of the interior. These caissons are brought to the site of the proposed pier, and are there sunk. Where the bottom is loose sandy earth, the Vacuum process, as it is termed, is often employed; that is, the air is pumped out from the interior, and the superincumbent pressure then causes the caisson to sink and the earth to rise within it. But it is more usual to employ what is called the Plenum process, in which air under high pressure is pumped into the caisson and expels the water, as in a diving bell. Workmen then descend, entering through an air lock, and excavate the ground at the bottom of the caisson, which sinks gradually as the excavation continues. Under this system a length of some two miles of quay wall is being constructed at Antwerp, far out in the channel of the River Scheldt. Here the caissons are laid end to end with each other, along the whole curve of the wall, and the masonry is built on the top of them within a floating cofferdam of very ingenious construction.

There are few mechanical principles more widely known than that of so-called centrifugal force; an action which, though still a puzzle to students, has long been thoroughly understood. It is, however, comparatively recently that it has been applied in practice. One of the earliest examples was, perhaps, the ordinary governor, due to the genius of Watt. Every boy knows that if he takes a weight hanging from a string and twirls it round, the weight will rise higher and revolve in a larger circle as he increases the speed. Watt saw that if he attached such an apparatus to his steam engine, the balls or weights would tend to rise higher whenever the engine began to run faster, that this action might be made partly to draw over the valve which admitted the steam, and that in this way the supply of steam would be lessened, and the speed would fall. Few ideas in science have received so wide and so successful an application as this. But of late years another property of centrifugal force has been brought into play. The effect of this so-called force is that any body revolving in a circle has a continual tendency to fly off at a tangent; the amount of this tendency depending jointly on the mass of the body and on the velocity of the rotation. It is the former of these conditions which is now taken advantage of. For if we have a number of particles all revolving with the same velocity, but of different specific gravities, and if we allow them to follow their tendency of moving off at a tangent, it is evident that the heaviest particles having the greatest mass will move with the greatest energy. The result is that, if we take a mass of such particles and confine them within a circular casing, we shall find that, having rotated this casing with a high velocity and for a sufficient time, the heaviest particles will have settled at the outside and the lightest at the inside, whilst between the two there will be a gradation from the one to the other. Here, then, we have the means of separating two substances, solid or liquid, which are intimately mixed up together, but which are of different specific gravities. This physical principle has been taken advantage of in a somewhat homely but very important process, viz. the separation of cream from milk. In this arrangement the milk is charged into a vessel something of the shape and size of a Gloucester cheese, which stands on a vertical spindle and is made to rotate with a velocity as high as 7000 revolutions per minute. At this enormous speed the milk, which is the heavier, flies to the outside, while the cream remains behind and stands up as a thin layer on the inside of the rotating cylinder of fluid. So completely does this immense speed produce in the liquid the characteristics of a solid, that if the rotating shell of cream be touched by a knife it emits a harsh grating sound, and gives the sensation experienced in attempting to cut a stone. The separation is almost immediately complete, but the difficult point was to draw off the two liquids separately and continuously without stopping the machine. This has been simply accomplished by taking advantage of another principle of hydromechanics. A small pipe opening just inside the shell of the cylinder is brought back to near the centre, where it rises through a sort of neck and opens into an exterior casing. The pressure due to the velocity causes the skim-milk to rise in this pipe and flow continuously out at the inner end. The cream is at the same time drawn off by a similar orifice made in the same neck and leading into a different chamber.

Centrifugal action is not the only way in which particles of different specific gravity can be separated from each other by motion only. If a rapid "jigging" or up-and-down motion be given to a mixture of such particles, the tendency of the lighter to fly further under the action of the impulse causes them gradually to rise to the upper surface; this surface being free in the present case, and the result being therefore the reverse of what happens in the rotating chamber. If such a mixture be examined after this up-and-down motion has gone on for a considerable period, it will be found that the particles are arranged pretty accurately in layers, the lightest being at the top and the heaviest at the bottom. This principle has long been taken advantage of in such cases as the separation of lead ores from the matrix in which they are embedded. The rock in these cases is crushed into small fragments, and placed on a frame having a rapid up-and-down motion, when the heavy lead ore gradually collects at the bottom and the lighter stone on the top. To separate the two the machine must be stopped and cleared by hand. In the case of coal-washing, where the object is to separate fine coal from the particles of stone mixed with it, this process would be very costly, and indeed impossible, because a current of water is sweeping through the whole mass. In the case of the Coppée coal-washer, the desired end is achieved in a different and very simple manner. The well known mineral felspar has a specific gravity intermediate between that of the coal and the shale, or stone, with which it is found intermixed. If, then, a quantity of felspar in small fragments is thrown into the mixture, and the whole then submitted to the jigging process, the result will be that the stone will collect on the top, and the coal at the bottom, with a layer of felspar separating the two. A current of water sweeps through the whole, and is drawn off partly at the top, carrying with it the stone, and partly at the bottom, carrying with it the fine coal.

The above are instances where science has come to the aid of engineering. Here is one in which the obligation is reversed. The rapid stopping of railway trains, when necessary, by means of brakes, is a problem which has long occupied the attention of many engineers; and the mechanical solutions offered have been correspondingly numerous. Some of these depend on the action of steam, some of a vacuum, some of compressed air, some of pressure-water; others again ingeniously utilise the momentum of the wheels themselves. But for a long time no effort was made by any of these inventors thoroughly to master the theoretical conditions of the problem before them. At last, one of the most ingenious and successful among them, Mr. George Westinghouse, resolved to make experiments on the subject, and was fortunate enough to associate with himself Capt. Douglas Galton. Their experiments, carried on with rare energy and perseverance, and at great expense, not only brought into the clearest light the physical conditions of the question (conditions which were shown to be in strict accordance with theory), but also disclosed the interesting scientific fact that the friction between solid bodies at high velocities is not constant, as the experiments of Morin had been supposed to imply, but diminishes rapidly as the speed increases—a fact which other observations serve to confirm.

The old scientific principle known as the hydrostatic paradox, according to which a pressure applied at any point of an inclosed mass of liquid is transmitted unaltered to every other point, has been singularly fruitful in practical applications. Mr. Bramah was perhaps the first to recognise its value and importance. He applied it to the well known Bramah press, and in various other directions, some of which were less successful. One of these was a hydraulic lift, which Mr. Bramah proposed to construct by means of several cylinders sliding within each other after the manner of the tubes of a telescope. His specification of this invention sufficiently expresses his opinion of its value, for it concludes as follows:—"This patent does not only differ in its nature and in its boundless extent of claims to novelty, but also in its claims to merit and superior utility compared with any other patent ever brought before or sanctioned by the legislative authority of any nation." The telescope lift has not come into practical use; but lifts worked on the hydraulic principle are becoming more and more common every day. The same principle has been applied by the genius of Sir William Armstrong and others to the working of cranes and other machines for the lifting of weights, &c.; and under the form of the accumulator, with its distributing pipes and hydraulic engines, it provides a store of power always ready for application at any required point in a large system, yet costing practically nothing when not actually at work. This system of high-pressure mains worked from a central accumulator has been for some years in existence at Hull, as a means of supplying power commercially for all the purposes needed in a large town, and it is at this moment being carried out on a wider scale in the East End of London.

Taking advantage of this system, and combining with it another scientific principle of wide applicability, Mr. J. H. Greathead has brought out an instrument called the "injector hydrant," which seems likely to play an important part in the extinguishing of fires. This second principle is that of the lateral induction of fluids, and may be thus expressed in the words of the late William Froude:—"Any surface which in passing through a fluid experiences resistance must in so doing impress on the particles which resist it a force in the line of motion equal to the resistance." If then these particles are themselves part of a fluid, it will result that they will follow the direction of the moving fluid and be partly carried along with it. As applied in the injector hydrant, a small quantity of water derived from the high-pressure mains is made to pass from one pipe into another, coming in contact at the same time with a reservoir of water at ordinary pressure. The result is that the water from the reservoir is drawn into the second pipe through a trumpet-shaped nozzle, and may be made to issue as a stream to a considerable height. Thus the small quantity of pressure-water, which, if used by itself, would perhaps rise to a height of 500 feet, is made to carry with it a much larger quantity to a much smaller height, say that of an ordinary house.

The above are only a few of the many instances which might be given to prove the general truth of the fact with which we started, namely, the close and reciprocal connection between physical science and mechanical engineering, taking both in their widest sense. It may possibly be worth while to return again to the subject, as other illustrations arise. Two such have appeared even at the moment of writing, and though their practical success is not yet assured, it may be worth while to cite them. The first is an application of the old principle of the siphon to the purifying of sewage. Into a tank containing the sewage dips a siphon pipe some thirty feet high, of which the shorter leg is many times larger than the longer. When this is started, the water rises slowly and steadily in the shorter column, and before it reaches the top has left behind it all or almost all of the solid particles which it previously held in suspension. These fall slowly back through the column and collect at the bottom of the tank, to be cleared out when needful. The effluent water is not of course chemically pure, but sufficiently so to be turned into any ordinary stream. The second invention rests on a curious fact in chemistry, namely, that caustic soda or potash will absorb steam, forming a compound which has a much higher temperature than the steam absorbed. If, therefore, exhaust steam be discharged into the bottom of a vessel containing caustic alkali, not only will it become condensed, but this condensation will raise the temperature of the mass so high that it may be employed in the generation of fresh steam. It is needless to observe how important will be the bearing of this invention upon the working of steam-engines for many purposes, if only it can be established as a practical success. And if it is so established there can be no doubt that the experience thus acquired will reveal new and valuable facts with regard to the conditions of chemical combination and absorption, in the elements thus brought together.

WALTER R. BROWNE

THE LITERATURE OF THE FISHERIES EXHIBITION[1]

II.

THE depopulation of our littoral fisheries is the text of a paper on "Crustacea," by Mr. T. Cornish, who proposes to meet the difficulty by establishing a market for "middle-sized" Crustacea (and even fishes), other than those which we now eat, either as "luxuries or dainties." There is an amusing but authoritative air of originality about this paper. Mr. W. S. Kent, on the other hand, proposes the "Artificial Culture of Lobsters" as a remedy for the same evil, and recounts some interesting experiments made by himself—on a small scale—in which he succeeded in rearing the young lobsters taken captive. The leading developmental phases are set down for the guidance of others, but the account given is deficient in record of the earlier stages of the process. This is important, as the writer (presupposing success such as has attended the artificial cultivation of the Salmonidæ) states, without apparent proof, that the cultivation might go on after the removal of the *eggs* from the parent. Should this be so, choice must then lie between the methods of Messrs. Cornish and Kent. The latter has overlooked the fact that our Irish lobster fisheries appear to be capable of much greater development, and we doubt how far an accusation brought against the "West-end chefs" is a logical one. We are at a loss to see the drift of Mr. K. Cornish's remarks, which form part of the discussion upon these two papers.

---

[1] Concluded from p. 36.

Early in the career of these meetings, our freshwater fisheries received attention at the hands of Sir Jas. Maitland, whose liberality in the matter of salmon-culture is well known in all fishing circles. The author, who regards the artificial propagation of the Salmonidæ as in its infancy, records the technique and results of a long practical experience, and indicates lines for future investigation, both as regards the migratory and non-migratory forms. He shows that by skilful attention he can rely upon hatching out 99 per cent. of Loch Levan trout ova, and, while discussing all sides of the question, he wisely points out that the object to be aimed at is "not to incubate the largest number of eggs in a given space," but so to manipulate them that "the largest number of healthy fish may result"—a statement involving difficulties for the study of which we must refer the reader to the paper itself. Intimately connected with this department is the question of the salmon-disease fungus, which forms the topic of a paper on "Fish Diseases," by Prof. Huxley. The author's investigations in the matter are well known to readers of NATURE, but all connected with freshwater fishing owe a debt of gratitude to the learned Professor for having thus sifted a voluminous literature upon the subject, and diagnosed in faultless style this pest. Its geographical limits are—for the first time—mapped out; the fungus is shown to *cause*, and not merely accompany, the disease, and its propagation is conclusively shown to be favoured by causes which though unknown must necessarily be limited. Every inducement is given to the daily worker among these fishes to cooperate in the further study of the disease, in even the purely scientific aspects of which much yet remains to be done. The remarkable fact that the disease is in no way correlated with the "productiveness" of a river is fully demonstrated, and must carry its own lesson.

A somewhat analogous topic forms subject-matter for a paper on "The Destruction of Fish by Internal Parasites," by Dr. S. Cobbold. There is, however, the most marked contrast between it and that of Prof. Huxley, and we venture to say that the statements made on the first two pages and elsewhere, are calculated to frighten rather than encourage (by appealing to the experimental side) possible workers in a field for which the author claims so much. We are compelled to put this work down with a feeling of disappointment, the more so seeing that much of the space which might have been turned to better account is devoted either to a mere reiteration of statements made again and again by the author during the earlier sittings of the Conference, or to needlessly lengthy and verbose discussions upon minor points, to the exclusion of more important ones.

The all-important topic of "Food of Fishes" is attacked by Dr. Day. There is much in his paper that is of value, he having incorporated the observations of others with his own to the best advantage. The extreme importance of this subject is obvious to all concerned, but when—to say nothing of the question of inter-preying—we consider the extent to which it is known that the food of fishes may vary under conditions of most of which we know absolutely nothing, it is obvious that there opens up a field of labour, involving all sorts of side issues, work in which must necessarily be both prolonged and tedious. The paper, however, suggests certain lines along which a fruitful advance might be made. In the discussion which followed, the chairman (Prof. Huxley), taking a philosophic grasp of the question, resolves it into a balance in favour of "the ultimate store of food" furnished by "the Diatomaceæ which occur on the surface."

Mr. R. B. Marston, in an exceedingly practical paper on "Coarse Fish Culture," adduces reasons for which it is obvious that repopulation of our fresh waters must go on as matters stand, and can be very beneficially maintained. The question is one of growing importance, especially as it affects those who, although living far inland, still have the power of rearing good fish-food. We doubt, however, how far it is not possible to obviate certain of the difficulties mentioned, by more careful "nursing" alone. In advocating the introduction of the prolific Black Bass, the writer makes a statement, partly borne out by the experience of the Marquis of Exeter who first introduced the fish into Britain, but diametrically opposed by that of Sir Jas. Maitland—and which, if correct, is of great importance—viz. that it "thrives best in just those waters which are *not* suited to trout and salmon."

It is well known that the natural salmon stock of five of our largest rivers is practically exterminated, and that the fish present themselves annually at their unsavoury mouths, but to be baffled by causes, chief among which is that of pollution; in other cases, less markedly offensive, the fish are known to be slowly but certainly receding The Hon. W. F. B. Massey Mainwaring, in a paper upon "The Preservation of Fish Life in Rivers by the Exclusion of Town Sewage," first points out the main causes of actual death, and then proceeds to advocate the claims of the well-known A.B.C. process, exhibited by the Native Guano Company. For this he claims success, greater than that which has attended any such known chemical method, all at present pointing to irrigation and intermittent-downward-filtration, as the best solution of the difficulty. All the artificial breeding in the world cannot be of avail in waters thus becoming more deadly, and to the chemist the utilisation of waste offers a good field for work. There are other doubtful points about this paper, beyond the limits of a short notice, but it is sincerely to be hoped that when the present inquiry into the London sewage question terminates, the adoption of some treatment beneficial to our waters may perpetuate its action.

Closely allied are the interests of "Forest Protection," advocated by Mr. D. Howitz, the more especially as there is evidence to show that the disappearance of salmon has been at times associated with the clearing of forests. The author points out that, while the question has naturally more interest for other countries than our own, it is possible to maintain throughout the year, by the interaction of natural forces, a better equilibrium of life in shallow water. Although much yet remains to be done in this work, the arguments adduced are practical and weighty. The author advises the use of certain trees as being, from his own experience, preferable, the question of growth of timber not being overlooked.

All the aforementioned papers point indirectly to the "outcome" of the present movement, in so far as they suggest methods of improvement. Those which remain are either directly addressed to that subject itself, or to others demanding immediate attention.

Prof. Leone Levi brings forward a mass of statistical knowledge upon "The Economic Condition of Fishermen," stated to be "generally unsatisfactory." The paper abounds in useful information, not the least important being that which deals with the relationships existing between boat-owners and fishermen; the author also states that at present the workers are in proportion excessive "to the amount of production," and wisely recommends a "weeding" of those parasites—neither fishermen nor fools—said to exist. The "fortunes of the fisheries and agriculture in the last twenty years" are significantly compared; but this and other matters dealt with are beyond the limits of our present notice.

In "The Principles of Fishery Legislation" the Right Hon. G. Shaw Lefevre, proceeding to deal with the sea fisheries, exclusive of Crustacea and littoral forms, recalls the circumstances which led up to the passing of the Sea Fisheries Act of 1868—the result of an inquiry before a Commission of which he was himself a member. This Act, essentially one repealing restrictive legislation and giving increased liberty, has lately, as our readers doubtless know, been much under discussion, and the statistics here brought forward speak for themselves as to the wisdom and successful working of the laws then laid down. When we consider the state of the question, as reviewed by the author, we must admit that to alter would be to mar such statutes as these, unless prompted by fresh acquisitions to our knowledge. Speaking of the littoral species, the author shows that restrictive action has exercised no beneficial influence whatever upon our oyster fisheries, and in connection with this subject good evidence has been brought before the Conference to show that actual harm has often been done by premature legislation. These considerations all point to a conclusion, reiterated again and again in the papers before us, and affording consolation to all save a small faction, which pleads injury, but for what reason we know not. This valuable paper is supplemented by one upon "The Basis for Legislation on Fishery Questions," by Lieut.-Col. F. G. Solá, Secretary to the Spanish Commission. Much of this paper is necessarily taken up in discussing Spanish fisheries, but the moral points in the direction indicated above. Speaking of "an absolutely restrictive system," the writer ably remarks that, "under the shade of those abuses established, recognised, or tolerated by former laws, there will have grown up a crowd of well-to-do interests, which it is not possible to disregard." These words and those which follow, will bear all the consideration we can give them.

Setting aside the popular sensational aspect of the "Fish Markets" question, of which those in authority have lately heard enough, that of "Fish Transports and Fish Markets" demands early consideration and prompt action. His Excellency Spencer Walpole, in dealing with it, confines himself to that "internal traffic" in which lie many sources of evil. Speaking of the necessity for railway reform, the author does not, as might be imagined, advocate State management, but seeks solution of the "suicidal policy" now existing, by insuring—between land and water carriage—a "healthy competition." All we can hope is that the matter may be thus easily rectified, meanwhile the fact remains that the future of great and important fisheries must depend upon the issue. The author enters into a discussion of the market question, but as so much concerning this rests with the City Corporation we await their views. Despite the protest lodged by Mr. Sayer on p. 20, we cannot but regard the silence of, and want of concerted action among, the Billingsgate men, as an unhealthy sign.

The perils of a fishing life are patent to all, and when we hear a cry raised on all hands for increased harbour accommodation, and read that the failure of our fisheries is often due to want of weather forecasts, it is obvious that an important claim is established. Mr. Scott, in a paper on "Storm Warnings," brings a well-known experience to bear upon this matter, and compares our own condition and apparatus with those of other countries, notably the United States, Germany, and Holland. Our greatest need at present is shown to be want of observatories on the west coasts of Ireland and Scotland, and the author points out the significant fact that "storm signals are hoisted at 111 stations only over the whole United States, while we in these islands have nearly 140 for a much smaller area." Speaking of the famed American storm-warnings, the need of mid-ocean observatories is discussed, as the storms almost invariably "change their character *en route*." Much other valuable information is embodied in this paper.

Prof. Lankester, writing on "The Scientific Results of the Exhibition," after making some admirable remarks about the "so-called practical man" and other topics, sets up a plea for a zoological observatory or "station." While no one will fail to enter into the spirit of his paper, we are of opinion that the plan—as concerning fisheries alone—need not be so elaborate as that suggested by him. No subject has created a greater revolution in the minds and actions of fishermen of late, than the discovery of Profs. Sars and Malm that the eggs of certain of our deep-sea fishes develop at the surface, and even were this not so no one would gainsay Prof. Lankester's cry of "more zoology." When we read that "the herring fishery is a lottery," and that simply because we know nothing of the real nature and causes of the movements of those fishes, it is quite obvious in what direction our earliest observations must be pursued. For this purpose a transportable zoological laboratory, with proper boats and appliances, such as that used in the recent successful experiments in the Netherlands, would amply suffice, and we conceive of such as best embodied in "A National Fishery Society," for which Mr. Fryer urges a strong, and it seems to us an exceedingly just, claim. All modern advance in the fishing industry points to the conclusion that Governmental action must be slight but firm; this being so, both common sense and precedent show it to be absolutely necessary that some such mediating body as that which the author would have established, should exist. Such a society would, of necessity, acquire in time all necessaries for work and progress, but, until this stage at least is reached, Britain—whose waters are second to none—cannot hope to hold her own in the matter of International Fisheries. We heartily recommend our readers to reflect upon a speech, made by Mr. Birkbeck, M.P., Chairman of the Executive Committee, which follows the aforementioned paper.

Such are the aims and scope of the Literature of the Great International Fisheries Exhibition, and when the remaining publications are forthcoming it will form a collection upon which both the fishermen and all concerned must be congratulated. It has been impossible to do more than indicate the general line of work in this brief notice, no note having been taken of the extent to which certain papers overlap; it will be obvious, however, where abuse lies, where reform is needed, and along what lines the expected "outcome" must proceed.

The style of these books, produced by Messrs. W. Clowes and Sons, leaves nothing to be desired; the few typographical errors which occur being unavoidable in dealing with the technicalities of such an extensive subject.

NOTES

THE adjudication of medals for the present year by the Council of the Royal Society is as follows:—The Copley Medal to Prof. Sir William Thomson, F.R.S., for (1) his discovery of the law of the universal dissipation of energy; (2) his researches and eminent services in physics, both experimental and mathematical, especially in the theory of electricity and thermodynamics; a Royal Medal to Prof. T. A. Hirst, F.R.S., for his researches in pure mathematics; a Royal Medal to Prof. J. S. Burdon-Sanderson, M.D., F.R.S., for the eminent services which he has rendered to physiology and pathology, especially for his investigation of the relations of micro-organisms to disease, and for his researches on the electric phenomena of plants; the Davy Medal to Marcellin Berthelot, For. Mem. R.S., and Prof. Julius Thomsen for their researches in thermo-chemistry.

Prof. Huxley and Sir Joseph Hooker having been elected members of the Salters' Company, were present at a dinner given by the Company on Tuesday evening, and both took praiseworthy advantage of the opportunity to remind our "City men" of some wholesome truths. Prof. Huxley said he had no doubt that an immense field of usefulness lay open for the Guilds and the Corporation of London. Happily it was a field which was not altogether unploughed, and one in which the road had been practically shown towards doing an immense amount of good. He wished to express an opinion which he had formed with great care, and which he uttered with a full sense of responsibility, that the work which had been undertaken in the name of the City and Guilds of London, and which had at present resulted in the foundation of an institute for technical education, was one of the greatest works, if properly comprehended, which had ever been taken in hand, whether they viewed it with reference to the commercial prosperity of the country, to its social organisation, or to the preservation of the condition of political equilibrium; for at the present time the wealth and prosperity of the country were a cloud generated out of the application of physical science, and taking that science away the cloud would vanish like any other baseless fabric of a vision. The future predominance of the commercial power of England depended upon whether its merchants had the wisdom to appreciate the gifts which science gave them. If, however, these elements were disregarded, London would perish as surely as Carthage. The social state and the preservation of the condition of political equilibrium depended, he argued, upon a proper knowledge of science. The institution to which he had referred provided for all those requirements, and it was one of the greatest privileges of the office which he at present held that he should be associated with those engaged in the organisation of this system, and who, he trusted, would carry on the enterprise to a successful conclusion.

The death is announced of the well-known American mineralogist, Mr. Lawrence Smith, at Louisville, Kentucky. Mr. Smith devoted himself mainly to the investigation of meteorites, and did much to increase our knowledge of these bodies. He was a corresponding member of the Paris Academy of Sciences.

Capt. Dawson and party of the British Circumpolar Expedition, which wintered at Fort Rae, Great Salt Lake, arrived safe and well at Winnipeg on November 2, having succeeded in crossing the height of land at Portage la Loche before the closing of the navigation by ice, which some of the resident authorities of the Hudson's Bay Company in the north-west thought they would be unable to do if detained on Slave Lake until the end of August.

M. Charcot, the chief surgeon of La Salpetrière, in Paris, has been nominated member of the Academy of Sciences.

It has beeen arranged that the tercentenary of Edinburgh University shall be celebrated on April 16, 17, and 18 next.

The results of the late Cambridge higher local examination were very discouraging as regards Group E (Natural Science). Only two out of sixty-six candidates gained a first class, and thirty-one failed. The following are extracts from the Examiners' reports:—Elementary Paper: The answers indicated an imperfect comprehension of principles, and an inadequate practical acquaintance with the subject-matter of the various sciences. In Chemistry the papers as a whole were markedly inferior to those of last year, showing want of knowledge of any practical arrangements for the simplest experiments. In Physics the work of all the candidates was very poor. The general want of clearness and definiteness of expression was very noteworthy. No marks were gained for answers to the numerical questions, and in but few cases were they attempted. In Physical Geography and Geology the answers were on the whole unsatisfactory. The candidates seemed to have studied the subject chiefly in books, for though one or two showed proofs of having acquired some practical knowledge in the Museum, nearly all, when describing the physiography and stratigraphical geology of an English district, gave indications that their knowledge was gained by reading, and not by actual observation in the field. In Physiology the answers of different candidates were very unequal. Some were extremely good, while a considerable number showed ignorance of the most rudimentary facts. There was very little evidence of a personal acquaintance with minute anatomy. In Zoology most of the answers were characterised by vagueness, want of precision, and a marked, often grotesque, ignorance of the meaning of the most ordinary technical terms. The reading of most of the candidates seems to have been very diffuse and unintelligent, while not one of the candidates had any real grasp of the principles of the subject. In Botany the answers were very weak. They indicated a tendency to neglect the external morphology and anatomy, and to pass on to special morphology and life-histories of the lower forms before the above-named branches of the subject had been properly mastered.

Among the lectures to be given at the London Institution during the coming season are the following:—December 3, Mr. G. J. Romanes, F.R.S., Instinct; 6, Rev. W. Green, the High Alps of New Zealand; 13, Prof. G. W. Henslow, the Glaciers of the Alps; 20, Prof. W. H. Flower, F.R.S., Whales; 27, Prof. H. Armstrong, F.R.S., Water (juvenile lecture); 31, Dr. Rae, F.R.S., the Eskimos and Life among them. January 3, Dr. Donald MacAlister, How a Bone is built; 7, Mr. H. Seebohm, Arctic Siberia; 10, Mr. Alfred Tylor, Celtic and Roman Britain; 17, Mr. H. Dixon, Explosives. February 7, Mr. Norman Lockyer, F.R.S., the last two Eclipses of the Sun; 18, Mr. J. Bryce, M.P., D.C.L., an Ideal University; 21, Prof. R. S. Ball, F.R.S., the Doctrine of Evolution applied to the Solar System; 25, Dr. E. B. Tylor, F.R.S., the Three Sources of History—Records, Monuments, and Social Laws. March 6, Prof. Schuster, F.R.S., the Aurora Borealis.

Herr Carl Rohrbach of Leipzig has lately described a method of procuring a fluid having extraordinarily high refractive and dispersive powers. 100 parts of iodide of barium are mixed with 130 parts of scarlet biniodide of mercury. About 20 c.c. of distilled water are added to the powders, and they are then stirred up with a glass rod while heated in a test tube plunged into an oil bath previously warmed to 150° or 200° C. A fluid double iodide of mercury and barium is formed, which is then poured into a shallow porcelain dish and evaporated down until it acquires a density so great that a crystal of epidote no longer sinks in it. When cold, even topaz will float in it. It is then filtered through glass-wool. The fluid so prepared has a density of 3·575—3·588, boils at about 145°, and is of a yellow colour. Its refractive index is 1·7755 for the C line, and 1·8265 for the E line of the spectrum. For the two D lines of sodium the refractive indices are 1·7931 and 1·7933 respectively. So great is the disperson that, using a single hollow prism with a refracting power of 60°, the dispersion between the two D lines is almost exactly 2′ of angle.

The latest official report of the Imperial German Post Office states that at the end of October the telephone was fully in operation in the following thirty-six cities and towns, within the Imperial postal territory (which does not include Bavaria or Würtemberg):—Aix-la-Chapelle, Altona, Barmen, Berlin, Beuthen, Brunswick, Bremen, Bremerhaven, Breslau, Burstcheid, Charlottenburg, Chemnitz, Cologne, Crefeld, Deutz, Dresden, Düsseldorf, Elberfeld, Frankfort-on-Main, Gebweiler, Geestemünde, Hamburg, Hanover, Harburg, Kiel, Königsberg, Leipzig, Magdeburg, Mayence, Mannheim, Mülhausen (in Alsace), Potsdam, Stettin, Strasburg, Sulzmatt, and Wandsbeck. In

four other towns—Halle, Karlsruhe, M. Gladbach, and Rheydt—the arrangements for its introduction have progressed so far that it will most probably be in operation in them before the end of this year. It is therefore likely that by the end of 1883 forty towns within the Imperial German postal territory will possess the advantages of the telephone, against twenty-one last year, and seven in October, 1881.

THE programme of the Yorkshire College Students' Association for the present session is a varied and interesting one. A "Yorkshire College Photographic Club" has recently been formed, and has already a good roll of members, including several members of the College staff. A prize competition has been arranged, and the Society has every prospect of success. The secretary of the Photographic Club is Mr. W. O. Senior.

ONLY six months ago a Society of Natural Science was formed at Bournemouth, and already it has 103 members, the president being Prof. Allman, F.R.S. The Society being established upon the most comprehensive basis, recognises every department of physical science as coming within the scope of its investigations. It is open to all, without limitation of class or sex. During the past session various papers have been read, and during the summer months bi-weekly morning and evening walks were taken under the leadership of the appointed heads of sections for botany, entomology, marine and terrestrial zoology and geology. The Committee contemplate devoting part of its funds to be awarded annually as prizes for the best and most systematically arranged collections of natural history specimens, made solely by each exhibitor, as an inducement to the younger members to cultivate habits of careful observation and systematic study of nature. The Society held a very successful *conversazione* on the 7th inst. at Bournemouth, and so attractive was the exhibition connected therewith, that it was kept open the following day. Captain Hartley, chairman of the Bournemouth Improvement Commission, opened the *conversazione* by giving some account of the origin and objects of the Society. The exhibition was of a very varied and instructive character, and at intervals during the day short popular lectures were given on such subjects as air, sound, the moon, natural magic, while the Rev. G. H. West exhibited and explained from time to time various apparatus illustrating physical phenomena. Altogether the Society gives promise of a successful career.

MR. GEORGE MURRAY will deliver a lecture on the potato disease at the Parkes Museum of Hygiene, 74A, Margaret Street, Regent Street, on Thursday, the 22nd instant, at 8 p.m.

SEVERAL members of the French Chamber of Deputies having contended that the transmission of telegrams was not so easy with underground wires as with aërial lines, M. Cochery has invited a number of opponents and electrical engineers to demonstrate on the lines now in existence, that the difference, if there is any, is quite immaterial.

AT a recent meeting of manufacturers and artisans convened by the Mayor at Coventry, resolutions were enthusiastically carried in favour of the adoption of a system of technical education in the city. It is proposed to provide a building for the consolidation and extension of the science classes, a lecture-hall, and reading-room, with a reference library of works appertaining to trade and manufactures, and to establish in connection with these three workshops for the practical teaching of mechanics (toolmaking, weaving, and watchmaking). It is estimated that about 4000*l.* will be needed for the building, and 3000*l.* for the fixtures and equipment of the building and workshops, in addition to which it will be necessary to provide an annual income of at least 300*l.* Subscriptions and donations exceeding 1000*l.* were promised at the meeting.

THE piercing of the Arlberg Tunnel, which will be 10,270 metres long, thus ranking third in the world, was expected to be completed to-day. The work began on November 13, 1880, on the western and eastern sides simultaneously, and has therefore lasted just three years, instead of four, as was calculated. Special trains will bring over two hundred invited guests from Austria, Italy, and Switzerland, to witness the final boring and the connection of the two galleries.

MR. G. J. SYMONS writes to the *Times* to say that Miss Eleanor Nunes, who had been keeping an extremely accurate record of the fall of rain at Langtree Wick, Torrington, Devon, died last spring, having left the sum of 100*l.* to him "to be applied to meteorological purposes." Mr. Symons announces that he is prepared to consider applications from all parts of the kingdom for rain-gauges to be sent gratuitously on loan subject to very easy conditions, and to send them to all accepted applicants who reside five miles from any rain-gauge now at work, and the same distance from any other applicant.

THE *Romando* has arrived at Cherbourg after a journey of two months, from Cape Horn. The results of the wintering have been important, and the crew is in good health.

THE diminution of credit rendered inevitable by the state of French finances will bear very little on the Budget of Public Instruction; the work of building the Meudon Observatory will not be stopped, and is proceeding favourably.

WE learn from a trustworthy source that there is again talk of transporting the Paris Observatory to some distance from the city, to a site in the vicinity of the new Flammarion Observatory.

THE Portuguese Government has appointed the explorers Capello and Ivens to proceed again on an expedition to West Africa, for the purpose of completing their map of the province of Angola, and of exploring the Congo. The explorers will leave by the packet on December 6.

NEWS has reached Europe of the assassination of M. De Brazza, but it is conjectured that this is the French explorer's brother, and not the explorer himself.

IN our note on the Royal Society last week, Dr. Warren De La Rue's name was given incorrectly.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. C. R. Browne; two Red-tailed Guans (*Ortalida ruficauda*) from Tobago, West Indies, presented by Mr. Alfred C. Priestly; two Gold Pheasants (*Thaumalea picta* ♂ ♂) from China, presented by Mr. H. W. Tyler; two Bar-breasted Finches (*Munia nisoria*) from Java, presented by Mr. J. Abrahams; a Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. John Colebrook, F.Z.S.; two Long-eared Owls (*Asio otus*), European, presented by Mr. C. Purnchard; a Masked Parrakeet (*Pyrrhulopsis personata*) from the Fiji Islands, presented by Miss J. D. Smith; two Alligators (*Alligator mississippiensis*) from the Mississippi, presented respectively by Mr. Roland Bridgett and Mrs. M. E. Symons; a Peregrine Falcon (*Falco peregrinus*), European, a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, deposited; a Bennett's Wallaby (*Halmaturus bennetti* ♀) from Tasmania, two Black Wallabys (*Halmaturus ualabatus* ♂ ♂) from New South Wales, a Yellow-footed Rock Kangaroo (*Petrogale xanthopus* ♂) from South Australia, a Mexican Eared Owl (*Asio mexicanus*) from Mexico, a Downy Owl (*Pulsatrix torquatus*) from South America, an Annulated Worm Snake (*Vermecilla annulata*) from Western Australia, purchased.

MOVEMENTS OF THE EARTH[1]

II.

Measurement of Time

IT has been shown how, by the application of geometrical and optical principles, the measurement of angular space has been carried down to the 1/100th of a second of arc, such a quantity being 1/129,600,000th part of an entire circumference, and when such an accuracy as this has been attained, and the altitude or the azimuth of the sun, or moon, or any other heavenly body can be correctly stated with this exactitude, it will be seen how much better off in the way of defining positions is the modern astronomer than was Hipparchus with his 1/3rd, and Tycho Brahé with his 1/4th of a degree. To do this, however, is not enough. It is not only necessary accurately to define the position of a heavenly body, it is necessary also to know at what particular time it occupied that position. The next thing to be done, then, is to see how far we moderns have got in another kind of measurement, no longer the measurement of arc—the measurement of angular distance—but the measurement of *time*.

The measurement of time, however, is not quite so simple a matter as was the measurement of space. A certain angular measurement of space, or the angular distance between two bodies, whether that distance be a degree, or a minute, or a second, is a very definite thing, having a beginning and an end; but time, so far as we can conceive, has neither beginning nor end; so that the problem of the measurement of time has to be attacked rather in a different way. Here again it will be as well that the matter should be studied historically.

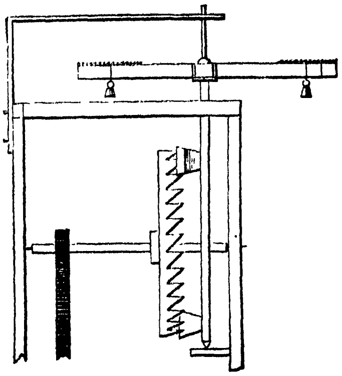

FIG. 18.—Ancient Clock Escapement.

What more natural than that man having got the idea of the flow of time, should have begun to measure it by the flow of water, or the flow of sand? The earliest time measurers were really made in this way; water or sand being allowed to drop from one receptacle to another. There were difficulties, however, in thus determining the flow of time. In the first place the thing was always wanting to be wound up, so to speak, something was wanted to continue the action, and to prolong it; and the first appeal to mechanical principles was made with that view.

The first real clock put up in England was put up in Old Palace Yard, in the year 1288, by the Lord Chief Justice of that time, who had to pay the expense of it as a fine for some fault he had committed. Its construction was somewhat after this wise. One method of dealing with the flow of time was to call in the aid of wheelwork; but, as is well known, if a weight acts upon a train of wheels the velocity increases as the rotation goes on. Therefore the science of mechanics was called in to supply some principle which could be applied to prevent this unequal velocity of a train of wheels. Consider the arrangement shown in Fig. 18.

The wheelwork train is capable of being driven by a falling weight. On the same axis as the smallest wheel, and therefore the one which turns most rapidly, will be seen another wheel provided with saw-like teeth. Then at the top is a weighted cross-bar, from the centre of which a perpendicular rod, provided with pallets, comes down to engage the teeth of the pallet-wheel. Now suppose the clock to be started. The weight is allowed to fall, and the wheels, including the pallet wheel, begin to revolve; then begins a reciprocating action between the swinging bar and the wheel with which it acts, because the pallets which act on the bar as they are on either side of the centre of motion really drive the bar first in one direction and then in the other. The teeth of the pallet wheel are continually coming into contact with the pallets of the swinging bar. First suppose that one of the teeth has encountered the upper pallet; it pushes this aside, and swings the bar in one direction. No sooner, however, has this been done than another tooth in the wheel at the bottom of the bar encounters the pallet and swings it in the opposite direction. In this way it is obvious that the bar is continually meeting and being met by the teeth of the rotating wheel, swinging first in one direction, and then in the other, the result of this reciprocal action being to prevent the increase in the velocity of the wheels which would otherwise take place.

It is in this way, then, by the performance at constant definite intervals of an equally constant definite amount of work, that the regularity of action of the clock is produced. The greater the distance of the weights on the cross-bar from its centre of motion, the longer will the bar take in swinging, the slower will be the action of the clock; so that the clock may be regulated by altering the position of these weights, bringing them nearer to, or removing them further from the centre of motion of the bar, according as it is desired to hasten or retard the action of the clock's mechanism. Yet at whatever distance from the centre of motion the two weights be placed, assuming always that they are both at the same distance from it, there is still this constantly-recurring performance, at equal intervals, of an equal amount of work which produces the regular action of the clock. This was the kind of clock then which was put up in Old Palace Yard. But that did not go well enough, giving such inaccurate results that Tycho Brahé had to discontinue its use. Fortunately some few years later two most eminent men, Galileo and Huyghens, had their attention drawn to this very problem. The first of these, Galileo, was at that time studying medicine. He happened one day to be in the Cathedral at Pisa, where, it will be remembered, they have a most beautiful lamp which swings from a great height in the cathedral. Galileo was at this time working at that branch of his medical studies which deals with the pulse, and he looked at this lamp and found that its swinging was perfectly regular. To-day perhaps it may seem very natural that this should be so, but Galileo had the advantage of being before us, and that is why it did not seem quite so natural to him. There was at that time no known reason why it should swing in perfect regular rhythm. He found that the lamp when swinging, no matter with what amplitude, took practically the same time for each swing, timing it by his pulse. His idea was that this would be an admirable method of determining the rate of a man's pulse, and the first clock on this principle was constructed from that medical point of view, being called a Pulsilogium. Some years afterwards, however, the extreme importance of such an arrangement from an astronomical standpoint became obvious, and very much attention was given to it. It is unnecessary to add that this swinging body is nowadays called a pendulum. The most perfect pendulum made in those early days is represented in Fig. 19.

The fundamental difference between that and the modern pendulum is that part of the pendulum between S and A was elastic. It was made elastic for the reason that although Galileo could not find any difference between the times of the oscillations of the lamp in Pisa Cathedral, according as its amplitude of swing was large or small, yet such a difference did exist, although it was only a slight one; and the only method of getting a perfect pendulum which should make its swing in exactly equal times, independent of its arc of oscillation, was to construct this so-called cycloidal pendulum. It was so named because in its swing its elastic portion was held by the curved guides seen in the figure, and made to bend in that particular curve. By this means the pendulum instead of swinging through the arc, K U R, was made to oscillate through D U L. But when the pendulum was at the points D and L, it was practically a shorter pendulum than when at rest. In other words, whilst the pendulum was swinging from U to D and from U to L, its curvature, and consequently its vibrating length was continually changing. In that way, by continually varying the length of the swinging part, it was found possible to make a pendulum which, independent of the length of its arc of oscillation, would make its swing in times which for all practical purposes were absolutely equal in length. That was the most perfect pendulum of that time. Nowadays, the cycloidal pendulum has been replaced by one which swings through a very small arc, and the continual shortening during the oscillation in the cycloidal pendulum is by this means dispensed with, whilst the friction also being much reduced, there is less interference from that source. With this very small swing the difference between the arc of the circle described and the cycloid in which the cycloidal pendulum swung is practically indistinguishable.

---

[1] Continued from vol. xxviii. p. 604.

The great difference between the modern clock and the ancient one is that in the former the pendulum is interfered with as little as possible whilst swinging, and makes each swing under precisely similar conditions. To attain this is to have done much. In the first place, if the clock has a heavy weight, that weight will probably interfere a good deal with the swinging of the pendulum. The clockweight, therefore, must be as light as possible. Secondly, if the wheelwork is always in contact with the pendulum, this also will interfere with its free and natural movement. There must be, then, such an arrangement that the wheelwork shall be brought into contact with the pendulum only for the shortest possible time. Thirdly, it must be remembered that the different substances which it is most convenient to use in the construction of pendulums, vary their dimensions with the variations of the temperature and moisture of the air in which they are placed, and great care must be taken to eliminate any errors which might arise from such a source. How are these various conditions complied with? The first, that the clockweight must be small, is not difficult to adhere to; but it will be well to consider the way in which the second condition, that the action between wheelwork and pendulum shall be the least possible, is met. This is done by employing what is called an escapement. It is so named because the pendulum in its swing is allowed to escape from the wheelwork, and thus retain a perfect freedom. The particular form of escapement about to be described is that which, for a reason that will appear immediately, is called the dead-beat escapement (see Fig. 20).

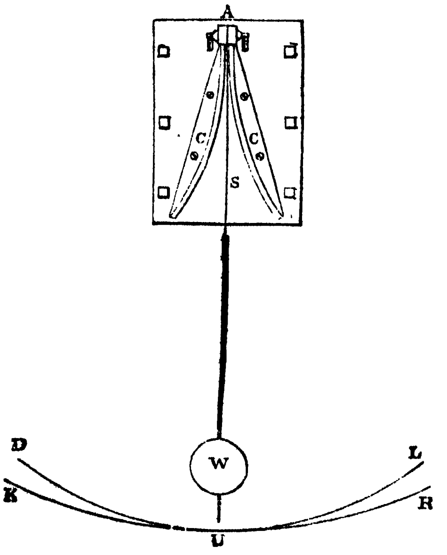

Fig. 19.—Cycloidal Pendulum.

The escape wheel is the modern representative of the toothed wheel of the old clock, whilst the projections W and D are modifications of the pallets on the swinging bar in that instrument. Let the pendulum move in the direction of the arrow. The tooth T has just been released, thus permitting the tooth V to engage the other pallet D. Now whilst the tooth remains on the pallet, the escape wheel remains locked, while the pendulum is quite free to swing, there being nothing to retard it save the very slight friction between the tooth and the surface of the pallet. The rotation of the escape wheels, however, brings the tooth on to the oblique edge of the pallet, and with it in this position the pendulum is aided in its forward swing. Then the pallet escapes, receiving an impulse, but since this is received almost as much before the pendulum has reached its vertical position as after it has passed that point, no increase or diminution in the time of its oscillation takes place. It is in this way that the second of our conditions is complied with, the wheelwork being effectually prevented from interfering with the regularity of the pendulum's swing. It is called the dead-beat escapement, because when the tooth falls on the circular portion of the pallet and locks the escape wheel, the seconds-hand fitted to it stops dead without recoil, because the arc of the surface of the pallet is struck from the centre of motion. In an astronomical clock a still more modern form of escapement, called the gravity escapement, is sometimes employed.

It will perhaps be convenient at this stage to compare the fineness of the division of time given by a clock of this description with the fineness of the division of the second of arc we have already discussed. There is, however, a little difficulty about this, because at present there seems to be no special reason why any particular unit of time should be selected. Ordinarily a day is divided into twenty-four hours, each of these twenty-four hours is subdivided into sixty minutes, these again being each divided into as many seconds. The origin of this division of time will be seen later on; for the present let the fact remain that it is so.

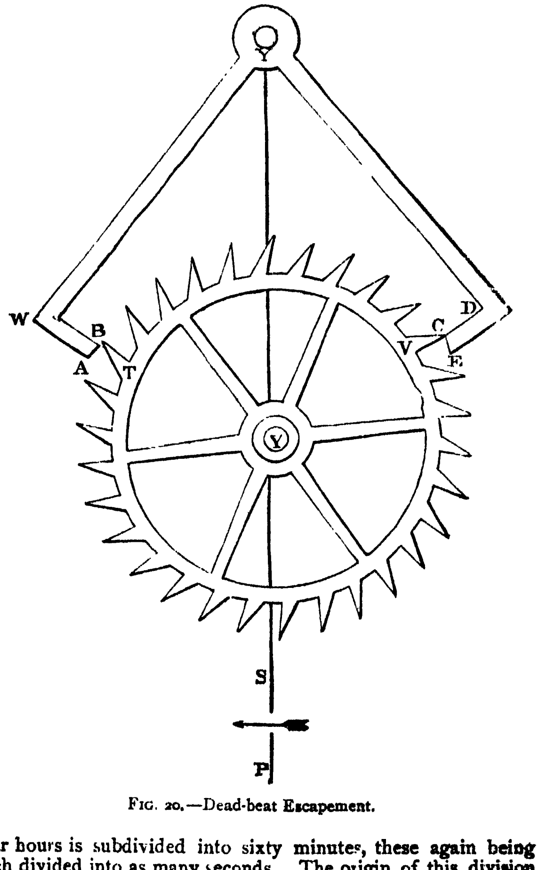

Fig. 20.—Dead-beat Escapement.

Now a modern clock beats practically true seconds, and astronomers after a little practice gain the power of mentally breaking that second up into ten divisions, each of which is of course one-tenth of a second, so that we can say that a day may be divided into 864,000 parts, and in this way institute a comparison of the fineness of the division of time with those minute measurements of angular space with which we so recently dealt.

It is a familiar fact that the length of a pendulum which vibrates seconds is some thirty-nine inches, and it is easy to understand that there are many conditions in which a clock of this kind, with its pendulum of more than a yard long, cannot be used. Not only indeed is there this inconvenient length of the pendulum, but it is necessary that the clock to which it belongs should be rigidly fixed in an upright position. The question therefore arises, is this clock which deals out seconds of such accuracy the only piece of mechanism that can record and divide our time, or is any other time-measuring instrument available? Fig. 21 shows part of such an instrument, known as the Chronometer, in which, whilst the principles necessary to be followed in the construction of the clock have been adhered to, the pendulum has been dispensed with, and the perfect stability and verticality of position so important to the clock, are here unnecessary.

In this instrument the pallets of the dead-beat escapement have been replaced by a detent, D. Let us consider the action. The escape-wheel, S, is advancing in the direction of the hands of a clock. One of its teeth meets the detent, and the wheel is locked. Then what happens is this: when the balance-wheel, R_1, swings, the circle, R_2, centred on it shares its motion. This, it will be seen, is armed with a little projection.

We left the escape-wheel locked. Now assume that the balance-wheel is swinging in the direction of the arrow. It carries the small circle with it, and the piece, P_2, in its motion, coming into contact with the end of the spring, seen projecting beyond the arm of the detent, raises it and the detent, so releasing the tooth of the escape-wheel. The slight retardation which the balance receives in consequence of this action is immediately compensated. The moment the escape-wheel moves on again, one of its teeth meets the projection, P_1, and the balance-wheel receiving this fresh impulse goes on to complete its swing. Then it returns and swings in the opposite direction, this time without acting in any way on the detent. When the balance-wheel made its first swing and the point P_2 met the projecting end of the spring, the latter could then only bend from the end of the arm with which the detent is provided and against which the point P_2 forced it. But on the return swing the spring is found capable of bending from the more distant point of its attachment to the shank of the locking-piece. It is therefore easily pushed aside; there is no change in the position of the detent, nor is any resistance offered to the motion of the balance-wheel, which goes on to complete its swing. Then another tooth is caught, the escape-wheel is again locked, and again released by the lifting of the detent. So the action goes on, the teeth of the escape-wheel being constantly detained and as constantly released by the action of the point P_2. The balance-wheel, it will be noted, receives its impulse only at every alternate swing, whereas in the clock the pendulum receives its impulse at each vibration.

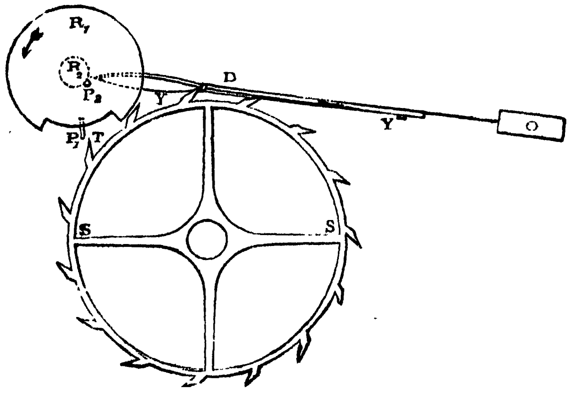

FIG. 21.—Chronometer Escapement.

Time then can be divided down to the 1/10th of a second, or as we expressed it, down to the 864,000th part of a day, not only by a clock, but also by this chronometer. Having obtained this 1/10th of a second by these instruments, the question arises as to whether it be possible to get a still finer division. It will be seen that a very much finer division than this can be obtained, the 1/100th part of a second being a measurable quantity; not that such a small fraction of time as this is ever necessary in astronomy, nor will it be until the present astronomical methods have ceased to exist. If it were possible to get all observations made by photography, then it would be worth while recording with such minuteness, because photography would always behave in the same way, whereas two observers never have the same idea as to the time of occurrence of any phenomena which they observe. Yet, although so great an accuracy as this is not attempted, it will be quite worth while to consider the means by which this exquisite fineness of the division of a second of time has been arrived at. We shall see that just in the same way as an appeal to mechanical principles resulted in an improvement in the construction of our clock, so this fineness in the division of time has been obtained by an appeal to the principles of electricity. Let it be assumed that the seconds pendulum of our clock swings with perfect accuracy and with absolute uniformity from second to second, in spite of changes of temperature and other perturbing influences; and having assumed this, let us see how electricity can be made to aid in the measurement of time. The instrument used is called a chronograph. It consists of a metal cylinder revolving by clockwork and covered with cloth, over which a piece of paper can be stretched. Below the cylinder and parallel with it is a track along which a frame carrying two electromagnetic markers or prickers is made to travel uniformly by the same clock that drives the cylinder. Wires connected with a battery lead from one of these magnets to a clock and from the other to a key, which can be depressed whenever an observation is made, and a current so sent to the magnet. The effect of this is to cause it instantaneously to attract its iron armature and cause the pricker with which it is connected to make a mark on the paper above.

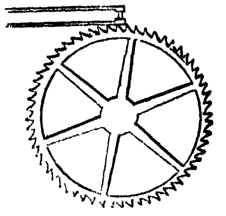

FIG. 22.—Electrical contact apparatus at back of clock.

The connection of the chronograph with the clock is as follows:—The bearing shown in the middle of the diagram (Fig. 22) is a continuation of the bearing on which the seconds hand of the clock is supported, and there is a little wheel which does its work quietly at the back of the clock in exactly the same way that the seconds hand does its work quietly in front of it. What that wheel does is this. Every time that each of its teeth—and there are sixty of them—comes to the top of the wheel it touches a little spring. That little spring then makes electrical contact, and a current is sent flowing through parts of the apparatus already described. Now the teeth in that wheel, being regularly disposed around its circumference, always succeed one another after exactly the same interval of time, and there is no difference or distinction from second to second, or from minute to minute. But suppose that before the clock is started one of these teeth is filed off, and so filed off that when the seconds hand points to 0 seconds, and the minute hand to a completed minute, this part of the wheel shall be at the top, and there shall be no electrical contact established, for the reason that the tooth of the wheel is not there to act on the spring. In that way it is easy to manage matters so that the beginning of each minute shall be distinguished from all the other fifty-nine seconds which make up the minute. Let the cylinder, covered with paper, revolve once in a minute. In that case, the electrical current will make a hole or a mark on that paper every second, and as matters are so arranged that the prickers shall be travelling along at the time that the dots are made upon the revolving paper they are thus made along a continuous spiral, and since we have supposed the cylinder to revolve once in a minute, the beginning of each minute will be in the same line along the spiral. Then, according to the length of the cylinder, a second of time will be obtained written in dots, sixty of them round the cylinder representing sixty seconds. Suppose now that a man with a perfect eye makes an observation, recording it by sending a current through the apparatus and making a dot on the paper. He will then have an opportunity of observing on the paper the precise relation of the dot which represents the time at which the observation was made to the other dots which represent the various seconds dotted out by the clock, and not only the exact distance of the observation prick from the nearest *second*, whether it be ½, or 1/10th, or 1/100th of the distance between that second and the next, but the omission of the record of the first second in the minute will give the relation that observation has to the nearest *minute*.

For the sake of simplicity the case of one observer making one observation has alone been considered; but if the work be properly arranged, then not only one electromagnet, but two, or three, or four, may be at work upon the same cylinder at the same time, each making its record, and that is how such work is being done at the Greenwich Observatory.

Observing Conditions

This power of measuring and dividing time then having been obtained, we seem to have reached our subject, "The Movements of the Earth." Yet even now there are one or two other matters which require to be discussed before we consider the movements themselves. The first of these is the important fact that the earth is spherical in its form. There have been many views held at different times as to the real shape of the earth, but the only view we need consider is that stated. In going down a river in a steamboat, or, better still, in standing upon the sea-shore at some place, such as Ramsgate, where there are cliffs, and where, consequently, one may get from the sea-level to some height above it, it is observed that when any ship disappears from our view by reason of its distance it seems to disappear as if it were passing over a gentle hill.

It does this in whatever direction it goes. This familiar fact is a clear proof that the earth is a sphere, and is so obvious that it may seem unnecessary to mention it, but it was as well to do so for a reason which will appear shortly. Besides this argument in favour of the spherical shape of the earth there is the argument from analogy: the moon is round, the sun is round, all the known planets are round. The stars are so infinitely removed from us that it cannot be determined whether they also are spherical, but doubtless they are as round as the earth. This point of the tremendous distance of the stars is an important one to bear in mind. Their distance cannot be conveniently stated by thousands, nor even by millions of miles, it is something far greater than that. It may be asked why it is that such a statement can be thus positively made. For this reason: the stars have been observed now for many ages, and the historical records of ancient times show that the chief constellations, the chief clusters of stars visible in the heavens now, were seen then. In the Book of Job, for instance, there is a reference to the well-known constellation of Orion, and there is very little doubt that for thousands and thousands of years that constellation has preserved the familiar appearance of its main features. The constellation called Charles's Wain, or the Great Bear, was also known to the ancients. If the stars were very near to the earth this could not be. If they were close to us the smallest motion either of earth or star would at once change their apparent position, and would prevent this fixity of appearance, and the skies would be filled, not with the constellations with which we are so familiar, but with new and ever-changing clusters of stars. This constancy of the constellations, not only from century to century, but from era to era, clearly proves then that the stars of which they are made up must be at an infinite distance from the earth.

B

FIG. 23.—Model to illustrate parallax.

Let us consider the question of distance a little further. If two pieces of wood (see Fig. 23) joined together by a cross-piece be taken, a moment's thought will make it obvious that the angles which A B and C B make with the cross-piece A C, will vary with the distance of the body, which can be seen first by looking along A B and then by looking along C B. If these pointers be directed to a very near object in the room, they must be greatly inclined (as in 1). If something more distant be taken, there is less inclination, and if it were possible to sight St. Paul's by looking first along A B and then along C B, there would be still less. And if something at a still greater distance were sighted, say St. Giles's at Edinburgh, the inclination of A B and C B would be still smaller than it was in the case of St. Paul's, because St. Giles's is at a much greater distance. It follows then that in sighting an object so infinitely removed from us as a star, the light from it will be in a condition of parallelism, and A B and C B consequently be placed quite parallel in viewing it (see 2). That is another reason for saying that the stars are at this infinite distance from the earth. Why it is so important to insist on this point will appear very clearly by and bye.

Now suppose that in the centre of this lecture-theatre a little globe were hung to represent the earth, the walls of the theatre and the people in it representing the heavens surrounding the earth. Now in such a case it is clear that the appearances presented would be the same whether the heavens moved round the earth or the earth itself were endowed with motion. Let us, without making the assertion, assume that the earth does move. It is perfectly obvious, since the apparent motions of the heavens are so regular, that if that be so she must move with wonderful constancy and regularity; she does not first move in one direction and at one inclination, and then at another; that would be very serious.

If she rotates she must rotate round some imaginary line called an axis. This introduces an important consideration because, whether the earth itself rotates on an axis or the heavens move round the earth—and in the latter case the heavens must also move round an axis—in either case the motion must be an equable one; so that if the matter is thus limited to a constant axial rotation or a constant revolution, as it would be called in the case of the stars, several things will happen. Let us take the former case, in which the earth itself moves. Then the motion of the surface of the earth will be least at those points which are nearest the ends of the axis on which it turns. Take the case of an observer at such a point, he will be carried a very little distance round during each rotation; similarly, if the stars move, a star near the ends of the axis on which the stars move will be carried a very little distance round during each revolution of the celestial sphere.

Change the position of the man on the earth from the pole to the equator. Then he will be carried a very considerable distance round in each rotation of the earth: similarly with the stars; if they move, a star in the celestial equator will be carried round a very great distance during a revolution. That is the first point. Another point is that if we assume the earth to rotate we must carefully consider the varying conditions which are brought about by the different positions of an inhabitant of the earth under those circumstances. For instance take the case of a man at the equator, he looks at things from an equatorial point of view, and in the rotation of the earth he plunges straight up and straight down. Similarly, if the stars' daily revolution belongs not to the earth but to the stars, to an observer at the equator of the earth they would appear to move straight up and straight down; and now in dealing with this question and endeavouring to ascertain whether it be the earth or the stars which move it is most necessary to consider the relation of the movements or apparent movements of the stars to the place from which they are observed, and in so doing it is found that there is an immense difference between the conditions which obtain at the poles and at the equator with reference to the phenomena which are observable in each case.

Let us take a globe to represent the earth, and let London be considered the central point for our observations. Now at all places on the earth, in whatever direction we look, we see an apparent meeting of earth and sky; and supposing our observation to be made on an extended plain or at sea, the surface of the earth or sea may for simplicity's sake be considered as a plane bounded by the circle where the earth and sky seem to meet. This is known as the circle of the horizon. To represent this, a piece of paper may be put over London on our globe (see Fig. 24), and London may be brought to the top. When that has been done, remembering that the stars are placed at so infinite a distance, the horizon which cuts the centre of the earth, and which is called the true horizon, may be considered as being practically the same thing as the small sensible horizon of London, represented by our piece of paper, when at the top of the globe, because the two planes will be parallel. For, whether a star be seen from the equator or from London, owing to its tremendous distance it will appear to occupy the same position in space. Now let the globe be made to rotate, then the inclination of the plane of the horizon of any place, of our horizon of London for instance, is continually changing during the rotation (Fig. 24). An exception, however, must be made with regard to the poles of the earth. At these two points the inclination will be constant during the whole of the rotation.

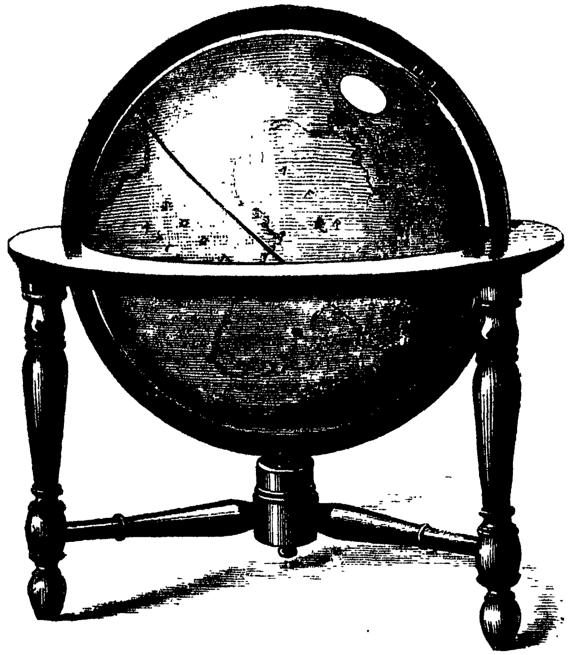

Fig. 24 —Diagram to show how the inclination of the horizon of London will change with the rotation of the earth.

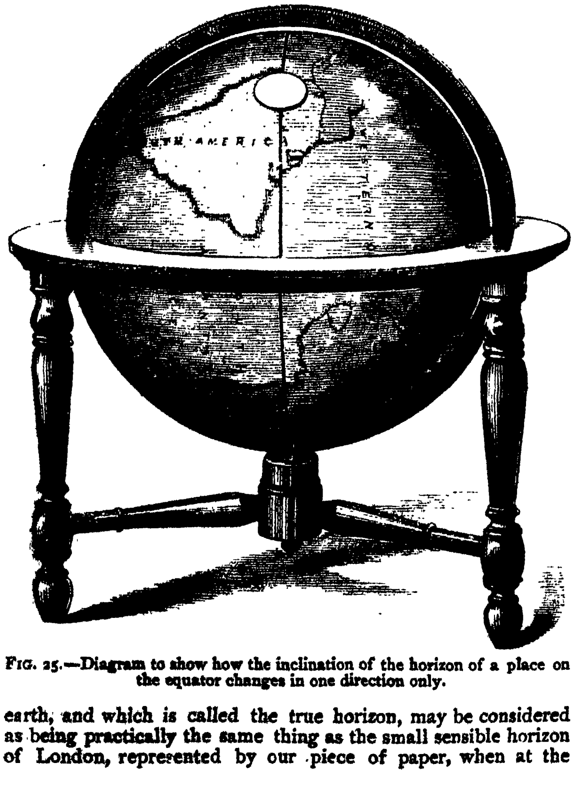

Fig. 25.—Diagram to show how the inclination of the horizon of a place on the equator changes in one direction only.

If now a point on the equator be brought to the top of the globe, it will be seen, as the globe is rotated, that the observer's horizon rapidly comes at right angles to its first position (see Fig. 25). This will show that the conditions of observation at different parts of the earth's surface are very different, and this whether it be the earth or the stars which move.

Let us now consider with a little greater detail the conditions which prevail in the latitude of London. Let London be again brought to the top of the globe. Let O (Fig. 26) represent an observer in the middle of the horizon, S W N E. Let Z be the zenith, which, of course, would be reached by a line starting from the centre of the earth, and passing straight up through the middle of the place of observation. S′ is a star, and we want to define its position. How can this be done? Imagine first a line drawn from the observer to the zenith. Imagine next another line going from the observer to the star, or, what is the same thing, from the centre of the earth to the star. Then the angle inclosed by these two lines will give us the angular distance of that star from the zenith, or similarly we may take the angle included between imaginary lines joining observer with horizon and star, and thus obtain the star's altitude.

Fig. 26.—Observing condition at London.

Again, its position may be stated not only with regard to the zenith and to the horizon, but to some other point, say the north point. In that case a line or plane, ZEW, is imagined passing from the zenith through the observer, and the distance between E and N will give the star's angular distance from the north point of the horizon. Again, suppose it be desired to define the star's position with reference, not to the zenith, but with reference to the pole of the heavens, that point where the earth's axis if prolonged into space would cut the skies. In that case since P in our diagram marks the position of the pole, a line PS′ will give what is called the polar distance of the star; and lastly, if the angular distance of the star from the equator of the heavens be required, since the prolongation of PS′ would cut the equator, the distance from S′ to the point of intersection will give the angular distance of the star from the equator; in other words its declination.

We have taken London, but of course each place on the earth has its sphere of observation with its zenith and the north, east, south, and west points. With regard to the axes of the earth and the heavens, they both possess north and south points, and in the heavens as in the earth, the equator lies midway between them.

J. Norman Lockyer

(*To be continued.*)

OUR ASTRONOMICAL COLUMN

The Observatory, Chicago.—Prof. G. W. Hough has issued his annual Report to the Board of Directors of the Chicago Astronomical Society, detailing the proceedings in the

Dearborn Observatory for 1883. The 18-inch Alvan Clark equatorial has again been employed in close observation of the great red spot and other phenomena of the planet Jupiter. Since the first observations at Chicago in September, 1879, it is stated that the red spot had not changed very materially in length, breadth, outline, or latitude. There had been a slow, retrograde drift in longitude, causing an apparent increase in the time of axial rotation. At the last opposition the deduced mean-rotation period was 9h. 55m. 38·4s. against 9h. 55m. 34·8s. in 1879.

Prof. Hough gives the following mean results of micrometrical measures of the red spot:—

	1879	1880	1881	1882
	″	″	″	″
Length ...	12·25 ...	11·55 ...	11·30 ...	11·83
Breadth ...	3·46 ...	3·54 ...	3·66 ...	3·65
Latitude ...	−6·95 ...	−7·14 ...	−7·40 ...	−7·52

The Chicago observer considers that while the spot has remained nearly stationary in latitude, the south edge of the great equatorial belt has gradually drifted south during the late opposition, until it is nearly coincident with the middle of the spot, and further, that "the two do not blend together, but are entirely distinct and separate." A depression formed in the edge of the belt (as shown in two drawings of the planet's disk, on December 29, 1882, and February 20, 1883), which corresponded in shape with the oval outline of the spot, the distance between the two being about a second of arc. The spot was extremely faint at the last observation for longitude on May 5. The equatorial white spot, first observed in 1879, was again visible during the last opposition; the rotation period 9h. 50m. 9·8s. deduced in the previous year, satisfying the observations.

The great comet of 1882 was micrometrically measured from October 4 to November 20, and sketches of the nucleus and envelope made. Subsequently to October 6 three centres of condensation were usually visible. As the comet receded from the sun, the head increased in length from 25″ on October 4 to 139″ on November 20. As late as March 6 there appeared to be three centres of condensation connected by matter of less density.

Difficult double-stars have been measured by Prof. Hough and Mr. S. W. Burnham, amongst them the interesting binaries, 40 Eridani (Σ 518), β Delphini, δ Equulei, and 85 Pegasi. Measures of the companion of Sirius gave for the epoch 1883.12 position 39°·9, distance 9″·04; the distance is diminishing about 0″·3 annually, so that in a few years it will be beyond reach of any except the largest telescopes. With the excellent measures obtained at Chicago more must soon be known as to the period of δ Equulei, reputed the most rapid of all binaries.

Tempel's Comet, 1873 II.—The following are places for Greenwich midnight, deduced from M. Schulhof's elements:—

1883	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth	Log. distance from Sun
Nov. 16 ...	18 20 48 ...	113 42·1 ...	0·2867 ..	0·1288
18 ...	18 28 22 ...	113 52·1 ...	0·2877 ...	0·1287
20 ...	18 35 59 ...	114 0·6 ...	0·2888 ...	0·1286
22 ...	18 43 38 ...	114 7·6 ...	0·2900 ...	0·1287
24 ...	18 51 19 ..	114 13·1 ...	0·2912 ...	0·1289

This comet approaches pretty near to the orbit of the planet Mars; in heliocentric longitude 312° (equinox of 1878), corresponding to true anomaly 6°·1, the distance is 0·050.

D'Arrest's Comet.—M. Leveau's ephemeris of this comet terminates on November 25. The following places are reduced from it to 6h. Greenwich M.T.:—

1883	R.A. h. m. s.	N.P.D. ° ′	Log. dist. from Earth	Intensity of light
Nov. 16 ...	17 15 44 ...	105 13·3 ...	0·3637 ...	0·084
17 ...	17 18 51 ...	105 22·1		
18 ...	17 21 59 ...	105 30·8 ...	0·3628 ...	0·086
19 ...	17 25 8 ...	105 39·3		
20 ...	17 28 19 ...	105 47·7 ...	0·3620 ...	0·087
21 ...	17 31 30 ...	105 55·8		
22 ...	17 34 43 ...	106 3·7 ...	0·3611 ...	0·089
23 ...	17 37 57 ...	106 11·5		
24 ...	17 41 12 ...	106 19.1 ...	0·3603 ...	0·090

M. Leveau mentions that when Prof. Julius Schmidt last observed the comet at Athens in 1870 with a refractor of 0·17m. aperture the intensity of light was 0·150.

On November 16 the comet sets at Greenwich 2h. 10m. after the sun.

The planetary perturbations during the next revolution are not likely to be large, so that in 1890 the comet may be observed under similar conditions to those of 1870.

STANDARD RAILROAD TIME

THE following letter, addressed to our American contemporary *Science*, is of interest:—

Though the subject of standard and uniform railway time has for some years been under consideration by various scientific and practical bodies, it does not appear in any way to have been exhausted, even in its main features. Besides, a certain bias has shown itself in favour of the adoption of a series of certain hourly meridians, and thus keeping Greenwich minutes and seconds, when contrasted with the practicability of a more simple proposition. There is also a feature in the discussion of the subject which bears to have more light thrown upon it: namely, what necessary connection there is between the railway companies' uniform time and the mean local time of the people, or the time necessarily used in all transactions of common life. Directly or by implication, certain time-reformers evidently aim at a standard time, which shall be alike binding on railway traffic as well as on the business community; and to this great error much of the complexity of the subject is to be attributed, and it has directly retarded the much-needed reform in the time-management of our roads.

We say all ordinary business everywhere must for ever be conducted on local mean solar time, the slight difference between apparent and mean time having produced no inconvenience; and we may rightly ask the railway companies to give in their time-tables for *public* use, everywhere and always, the mean *local* time of the departure and of the arrival of trains. It is the departure from this almost self-evident statement, and the substitution and mixing-up in the time-tables of times referred to various local standards, which has in no small measure contributed to the confusion and perplexity of the present system. The people at large do not care to know by what time-system any railroad manages its trains, any more than they care what the steam-pressure is, or what is the number of the locomotive. All the traveller is interested in is regularity and safety of travel; hence it was to be desired that, whatever the standard or standards of time adopted, the companies would refrain from troubling him with a matter which only concerns their internal organisation, or which is entirely administrative. We look upon the publication of the railway time-tables, by local time everywhere, as a *sine quâ non* for the satisfactory settlement of the time question, so far as the public at large is concerned; and it would seem equally plain that the best system for the administration of railroads would be the adoption of a uniform time, this time to be known only to the managers and *employés* of the roads.

We are informed in *Science* of October 12 that the solution of the problem of standard railway time is near at hand, and probably has already been consummated by the adoption of four or more regions, each having uniform minutes and seconds of Greenwich time, but the local hour of the middle meridian. To have come down from several dozen of distinct time-systems to a very few and uniform ones, except as to the hour, is certainly a step forward, and, so far, gratifying; but why not adopt Greenwich time, pure and simple, and have absolute uniformity? Probably this will be felt before long. The counting of twenty-four hours to the day in the place of twice twelve, and the obliteration from time tables of the obnoxious a.m. and p.m. numbers, would seem to be generally acknowledged as an improvement and simplification, and perhaps can best be dealt with by adopting it at once, accompanied by a simple explanatory statement.

C. A. Schott

Washington, October 18

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

Oxford.—No election has yet taken place either for the Professorship of Botany or that of Rural Economy, which are now separated from each other. The Delegates of the Common University Fund have agreed to attach a Readership to the Chair of Botany, which will raise the income to 500*l.* a year. The

Professorship of Rural Economy will not be a resident one. The Professor will have to deliver twelve lectures. His stipend is 200*l*. a year.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, November 8.—Prof. Henrici, F.R.S., president, in the chair.—The following resolution, proposed by the President and seconded by Dr. Hirst, F.R.S., was carried unanimously, viz.:—"That the secretaries be requested to communicate to Mrs. Spottiswoode the expression of our sincere sympathy and the assurance of our deep sense of the loss which science has sustained by the untimely death of Mr. Spottiswoode."—The new Council was elected for the session 1883–84, viz.: Prof. Henrici, president; Sir J. Cockle, F.R.S., and Mr. S. Roberts, F.R.S., vice-presidents; Mr. A. B. Kempe, F.R.S., treasurer; Messrs. M. Jenkins and R. Tucker, honorary secretaries; other members, Prof. Cayley, F.R.S., Messrs. E. B. Elliott, J. W. L. Glaisher, F.R.S., J. Hammond, H. Hart, Dr. Hirst, F.R.S., W. D. Niven, F.R.S., Prof. Rowe, and Messrs. R. F. Scott and J. J. Walker, F.R.S. The Rev. J. J. Mylne and Mr. F. W. Watkin were elected members. —The following papers were communicated:—Symmetric functions, and in particular on certain inverse operators in connection therewith, Capt. P. A. Macmahon.—On a certain envelope, Prof. Wolstenholme.—On certain results obtained by means of the arguments of points on a plane curve, R. A. Roberts.—Third paper on multiple Frullanian integrals. E. B. Elliott.—Note on Jacobi's transformation of elliptic functions, J. Griffiths.—Symmedians and the triplicate-ratio circle, R. Tucker.

Linnean Society, November 1.—Frank Crisp, treasurer and vice-president, in the chair.—Messrs. T. E. Gunn and A. Hutton were elected Fellows.—A donation to the Society of several interesting letters of Linnæus (1736–1769) to G. D. Ehret, F.R.S., an eminent botanical artist of the last century, was announced by the Chairman, and a unanimous vote of thanks thereupon accorded to the Misses Grover and Mr. Chas. Ehret Grover for their valuable donation.—Mr. Crisp drew attention to specimens in fluid medium of *Limnocodium sowerbii*, as illustrative of Mr. P. Squires' method of preserving delicate and other medusæ.—Mr. H. Groves showed examples of *Chara braunii* from Ashton-under-Lyne, and Mr. Arthur Bennett of *Najas marina* and *N. alagnensis* from Hickling Broad, Norfolk, all being new to the British flora.—Mr. W. Fawcett exhibited *Testacella maugei* alive, the same being obtained by J. C. Mansel Pleydell in Dorset, and supposed to be indigenous to that county.—A paper was read on the changes of the flora and fauna of New Zealand, by Dr. S. M. Curl. He referred more particularly to the district of Rangitikei and to the alterations of the aspect of the vegetation within the last forty years. He likewise records his own experiments in the cultivation of trees, shrubs, and flowering plants introduced from widely different climes, remarking that while a few fail to grow with vigour, the majority by degrees adapt themselves to the altered conditions, and many valuable economic plants thrive accordingly.—Mr. J. Starkie Gardner read a paper on *Alnus richardsoni*, a fossil fruit from the London Clay of Herne Bay. The species has been described by Bowerbank and commented on by Carruthers, Ettinghausen, and many other authors who have written upon the plants of the Tertiary formation. Originally considered as allied to *Casuarina*, Dr. R. Brown suggested its affinities to the Proteaceæ, a view afterwards upheld by Carruthers and others. Ettinghausen thereafter regarded it as a product of a Conifer (*Sequoia*), and Saporta compared the fruit to that of *Dammara*. Mr. Gardner enters fully into the structural peculiarities of the fossil fruit in question, and satisfactorily demonstrates that it belongs to the Betulaceæ under the genus *Alnus*. —Another paper by Miss G. Lister was read, viz. on the origin of the Placentas in the tribe Alsineæ of the order Caryophylleæ. This communication is based on a series of observations on the development of a number of genera and species. She concludes that the capsule in the Alsineæ is developed on essentially the same plan as that of *Lychnis*, the difference in the various genera being merely dependent upon the relative height attained by the carpels on the one hand, and by the central axis on the other. This being so, we are bound to admit that if we accept, as we do, the carpellary origin of the placentas in *Lychnis*, the placentas in the Alsineæ, from *Sagina apetala*, which most resemble *Lychnis*, to *Cerastium triviale*, which most widely differs from it, are also carpellary.

Chemical Society, November 1.—Dr. Perkin, F.R.S., president, in the chair.—The following papers were read:—On the production of hydroxylamine from nitric acid, by E. Divers. Free nitric acid yields hydroxylamine when treated with tin, zinc, cadmium, magnesium, and aluminium. In the presence of hydrochloric or sulphuric acid the quantity with tin or zinc may be considerable. Without a second acid only traces can be detected. The author also discusses the action of nitric acid upon metals and the constitution of nitrites, in which he considers the metal to be directly united with nitrogen.—On the chemistry of lacquer (*Urushi*) (part i.), by H. Yoshida. Lacquer contains a peculiar acid, Urushic acid, extracted by alcohol, some gum resembling gum arabic, water, and a peculiar diastatic body containing nitrogen. The lacquer when exposed to moist air at 20° C. dries up into a hard lustrous varnish. This hardening is brought about by the action of the diastase upon Urushic acid, the latter being converted into oxy-urushic acid.—On some compounds of phenols with amidobases, by G. Dyson. The author has prepared and investigated anilin phenate, toluidin phenate, naphthylamin phenate, anilin β naphthate, toluidin naphthate, rosanilin phenate, xylidin naphthate, rosanilin aurinate, anilin aurinate.—On the alleged decomposition of phosphorous anhydride by sunlight, by R. Cowper and V. B. Lewes. In a paper at the British Association, Southport, the Rev. A. Irving stated that phosphorous anhydride prepared by passing air over heated phosphorus is decomposed by sunlight into phosphorus and phosphoric anhydride. The authors find that phosphorous anhydride thus prepared consists of a mixture of phosphoric anhydride, phosphorous anhydride, and phosphorus.

Physical Society, November 10.—Prof. Clifton in the chair.—Dr. J. Blaikley read a paper on the velocity of sound in air, in which he described a modification of Dulong's method of measuring it by the wave-length in a pipe lengthened. Dulong did not allow for the partial tones, which are an important factor, whereas Mr. Blaikley does. By means of organ pipes of different diameters, the author has found the velocity to be about 320 metres per second. Mean result with four tubes: one of 54·1 mm. diameter, velocity = 329·73 metres per second; one of 32·5 mm. diameter, velocity = 328·78 metres; one of 19·5 mm. diameter, velocity = 326·9 metres; one of 11·7 mm., velocity = 324·56 metres. The velocity diminishes as the tube is smaller in bore.—Mr. Bosanquet made a communication on the moment of a compound magnet, which he showed how to measure by the method already published by him. A compound magnet made up of eighteen small cylinders of magnetised steel placed end to end is hung in a cradle carried by a delicate bifilar suspension, and placed at right angles to the magnetic meridian. The deviation from zero produced by the magnet is noted; then the magnet is divided into two parallel rows of nine cylinders along the cradle, and the deviation again noted. The tangent of the angle of deviation from the east and west line, multiplied by a constant, is the moment of the magnet. The author also pointed out that to define the condition of a permanent magnet it was necessary to know the difference of magnetic potential, the "resistance" of the metal, and the resistance of the external space. —Mr. W. Lant Carpenter read a paper on measurements relating to the electric resistance of the skin, and certain medical appliances. The author's experiments, made upon himself, showed that the resistance of the body amounts to thousands of ohms, but is mainly due to the condition of the epidermis. If this is dry, the resistance is high. By soaking the skin in salt and water, he reduced the resistance of parts of his body from 10,300 ohms to 935 ohms after 100 minutes' soaking. He infers that a large electrode should be used in applying electricity to the body, and that the skin should be soaked for twenty-five minutes previously. Mr. Carpenter also exhibited a "chain-band" of Mr. Pulvermacher, and a small voltameter by the same inventor, in which the liberated gases force some of the water up a graduated tube as a gauge of the current. The author drew attention to the necessity of seeing that the skin should be dry in handling some electric light machines, else disagreeable shocks might result. Prof. Ayrton believed that the danger of electric lighting currents lay rather in their discontinuity than their electromotive force. The Brush currents, which have proved fatal, are more discontinuous than those of the Gramme machine, &c. Adverting to the presence of electricity in the air as influencing health, he suggested that the influence might be studied by electrifying the air, say in a hospital ward. Mr. W. Coffin stated that statically electrifying patients had been tried at Bellevue Hospital, New York, without definite results.

PARIS

Academy of Sciences, November 5.—M. Blanchard, president, in the chair.—Funeral orations on the late M. Breguet, by M. Janssen and Admiral Cloué.—Notice by M. Daubrée of the death of Mr. Lawrence Smith, Corresponding Member for the Section of Mineralogy, who died at Louisville, Kentucky, on October 12.—On lighting by electricity, by M. Th. Du Moncel.—On one of the methods proposed by M. Lœwy for determining the right ascensions of the circumpolar stars, by M. F. Gonnessiat.—Remarks on M. Boussinesq's communication respecting the equilibrium of a ring subjected to normal pressure uniformly distributed, by M. Maurice Lévy.—Note on the decomposition of a number into five squares, by M. Stieltjes.—On the probability that a given permutation of *n* quantities is an alternating permutation, by M. Désiré André.—On the algebraic integration of linear equations, by M. H. Poincaré.—On a family of developable surfaces generated by the intersection of a given left curve at an angle depending exclusively on the coordinates of the point of intersection, by M. Lucien Lévy.—On the potential of the inductive force due to a closed solenoid with current of varying intensity; analogy with Felici's theorem of electromagnetism, by M. Quet.—On a new non-periodical galvanometer, by M. G. Le Goarant de Tromelin.—On the electric resistance of sulphur, phosphorus, and some other more or less insulating substances, by M. G. Foussereau.—On the influence of nitrate of soda and of nitrate of potassa on the cultivation of potatoes, by M. P. P. Dehérain.—Researches on the physiological properties of maltose, by M. Em. Bourquelot.—On the external application of metallic copper as a preservative against cholera, by M. Axel Lamm.—On the comparative toxic action of metals on microbes, by M. Ch. Richet.—Note on zooglœic tuberculosis, by MM. L. Malassez and W. Vignal.—On spermatogenesis amongst the edriophthalmous Crustaceans (genera Ligia, Idotea, Sphæroma, Gammarus, Talitrum), by M. G. Herrmann.—On internal sacculine, a fresh stage in the development of *Sacculina carcini*, by M. Yves Delage.—On the anatomical structure of the Phallusiadeæ, a family of Ascidians on the coast of Provence, by M. L. Roule.—On the intestinal cavity and sexual apparatus of *Spadella marioni*, by M. P. Gourret.—A second contribution to the history of the formation of coal, by M. B. Renault.—On a ferriferous meteorite which fell at Saint Caprais de Quinsac, Gironde, on January 28, 1883, by MM. G. Lespiault and L. Forquignon.—On the diurnal variation of the barometer at different altitudes, and on the existence of a third barometric maximum, by M. Ch. André.—Note on the periodicity of earthquakes, by M. Ch. V. Zenger.—On the employment of sulphuric acid in the treatment of animal matter infected by contagious elements, by M. Darreau.

BERLIN

Physiological Society, October 26.—In the course of his investigations into the functions of the cortex of the cerebrum, Prof. Munk had often had occasion to collect experiences on the subject of the appearance of general epileptic spasms resulting from irritation of the cortex of the cerebrum. By this means he had been enabled to confirm not only the older clinical conclusion of Mr. Jackson, that epileptic spasms always proceeded from one group of muscles, and then overtook in a perfectly definite series more distant groups, and at last the whole body, but likewise the accuracy of Herr Hitzig's observation, that in the case of more powerful or longer continued irritations of the motory parts of the cortex of the cerebrum, the contractions of the group of muscles belonging to the irritated spot ended in general epileptic spasms. An experimental epilepsy of this kind Prof. Munk could produce from any spot of the motory part (the sphere of feeling), and the groups of muscles therefore followed each other exactly in the series in which the centra were stratified beside each other in the sphere of feeling, so that first the parts situated nearest the irritated spot, and then more distant parts became affected, till at last the whole body was subjected to epileptic contractions. Sometimes the whole of the groups of muscles on one side was attacked before the other side began to be affected; frequently, however, the irritation and the epileptic attack passed over at an earlier stage from one side to the other. That the experimental epilepsy originated in the motory section of the cortex of the cerebrum seemed to Prof. Munk indubitably established by the two following facts:—Let a small piece, say the centre for the movements of the upper extremity of the right side, be excided, and let the centre of the eye-muscles be irritated till epilepsy set in, then would the spasmodic contractions propagate themselves successively to all groups of muscles with the exception of the right upper extremity, which would remain at rest throughout the epileptic attack. Let, again, the centre of the eye-muscles (a part specially suitable for such experiments) of an animal be irritated so that an epileptic attack supervened, and after a corresponding pause let the irritations be repeated in the same part with equal strength and duration, then, in the event of the spasms reaching the muscles, say of the head or neck, by suddenly removing the irritated part of the membrane the epilepsy would also be terminated. Both phenomena were explainable only on the assumption that the irritation of the motory cortex of the brain was the cause of the experimental epilepsy. The assertion was advanced by another observer, that epilepsy could be generated not only from the front section of the cerebral cortex, but likewise from the sphere of vision. This position Prof. Munk induced Herr Danilo to put to the proof, but in spite of numerous experiments no confirmation of it could be gained. Electric streams, of a force and duration such as, applied to any part of the sphere of feeling, would undoubtedly have given rise to epilepsy, were quite powerless in this respect when applied to the sphere of sight. Not till streams of much intenser force and very considerably longer duration were applied to the sphere of sight was an epileptic attack produced. In this case, too, it was obvious that the result was due to the neighbouring parts of the sphere of feeling becoming irritated through propagation of the effect or by communication. If now at the beginning of the epileptic attack the irritated part of the sphere of sight were removed, the attack would not thereby be stopped. Nor was it of any greater consequence in the way of producing an attack that by a cross cut the irritated sphere of sight was freed from its substratum, if only it retained connection with the front part of the cortex. Let, however, the sphere of sight, by means of a perpendicular sagittal cut, be separated from the sphere of feeling, then could no epileptic attack be any longer produced by irritating the former. These facts seemed to Prof. Munk to conclusively demonstrate that experimental epilepsy could be produced only by irritation of the motory parts of the cortex of the cerebrum. He laid stress, however, on the fact that his experiences and experiments referred only to "experimental" epilepsy.

THE GERMAN FISHERIES COMMISSION

ierter Bericht der Commission zur wissenschaftlichen Untersuchung der deutschen Meere für Jahre 1877-1881. II. Abtheilung. (Berlin: Paul Parez, 1883)

THIS portion of the Fourth Report of what might perhaps be called the German Fisheries Commission is a folio volume of considerable thickness, consisting exclusively of three elaborate scientific memoirs, each of which is stamped with the thoroughness so characteristic of German work. The first, by Dr. Adolf Engler, deals with the marine fungi of Kiel Bay, the second, by Dr. R. Möbius and Fr. Heincke, with the fish fauna of the Baltic, and the last contains an account of the properties and history of the eggs of certain fishes, by Dr. von Hensen.

The second, which we shall first consider, is the most important and the largest—extending to nearly 100 pages—and consists of an elegant and concise description of all the species of fish hitherto found in the Baltic. As the work is founded on observations extending over twenty years, made with the advantages of constant residence on the Baltic shore and of control over the collections in the Kiel Museum, the list is as valuable as it is complete. This makes the absence of some forms we should naturally have expected all the more remarkable: we have especially noticed the absence of Myxine, but perhaps to those better acquainted with the distribution of this interesting form its absence will not be a matter of surprise.

The descriptions are preceded by an introduction which explains in a very lucid manner the principal points of fish organisation and their relative importance in identification. This is followed by a simple classificatory catalogue of the fishes described. In this catalogue all Teleostei are divided into Physostomi and Physoclisti. It is satisfactory to find the great fundamental characters which divide the Teleostei insisted upon, but there seems no objection to retaining the criterion of the fin rays for the Physoclisti, especially as this criterion brings out the affinity between Gadidæ and Pleuronectidæ.

The concise and elegant descriptions are supplemented by a useful fin formula which makes comparison easy. The food and habits of the fish are mentioned, the spawning habits being especially described, and each account is accompanied by a simple but extremely well executed woodcut, in which all the characteristic features are definitely indicated in outline. The object stated in the preface, to make identification practicable to laymen, has been certainly attained.

In the account of the herring considerable space is given to the discussion of the differences between the two races which the labours of the Commission have shown to exist in the Baltic. Perhaps before long it will be ascertained whether the same differences exist between the spring and autumn herring of the North Sea.

The last portion of this memoir consists of general considerations on the fish fauna of the Baltic. The authors find that this sea may be divided into three regions, each characterised by a distinct fish fauna, of which the Western receives the greatest number of occasional visitors from the North Sea. They conclude that the Baltic was once in open communication with the Arctic Ocean, and that some of the species of fish which entered at that time remain now as inhabitants of the Gulfs of Bothnia and Finland. This portion of the work is illustrated by an interesting map. Appended to the whole is a table of the spawning periods of the fishes constantly inhabiting the Bay of Kiel, and also an index of the Latin names of the fishes described, and another of their German, Danish, and Swedish synomyms.

Dr. von Hensen reports at length on the researches made by him during four years on the eggs of the plaice, flounder, and cod.

Agassiz described the eggs of the plaice as floating at the surface, while the Swedish naturalist, Malm, affirmed that they slowly and gradually sink. The first eggs that Dr. Hensen obtained from a ripe female plaice gradually sank. This being a question of the relation between the specific gravity of the eggs and of the salt water, Hensen carried out a series of investigations into the specific gravity of the different eggs and their natural condition when deposited by the fish. By an elaborate process of measurement and calculation he arrived at the specific gravity of the ripe eggs before extrusion, and ascertained the limit of specific gravity and the salt percentage in the water which determines whether the eggs of the cod and plaice shall float or sink. He found that cod's eggs floated in water which contained more than 1·85 per cent. of salt; and plaice eggs, when the percentage was above 1·78. These correspond to a specific gravity of 10145 and 10136 respectively, at 17°·5 C. He found from the observations of the Commission that the water in the Bay of Kiel has very often a specific gravity less than these. Thus there is an exception even to the statement that cod's eggs float. As will be seen, they always float in the open ocean. It was found that the specific gravity of the eggs before extrusion was somewhat greater, and their volume somewhat less than in the fertilised eggs which had been in sea water, and further that the eggs swell somewhat by the absorption of water without salt.

The author next calculated, from the number of female fish taken on a given fishing-ground and the average number of eggs contained in each, the average number of eggs in the sea corresponding to a square metre of surface, and then made careful continuous nettings of the eggs to find if the actual number coincided. He fished the bottom, and the surface, and vertically. Eggs of the plaice and flounder were frequently taken at the bottom. He found the eggs pretty evenly scattered, and often obtained them in the proportion of 30-80 per square metre of surface. He then discusses what proportion of eggs are likely to be destroyed by their various enemies. This is the first attempt which has been made to estimate the actual number of eggs of fishes hatched in a particular area. The whole paper bears evidence of the most profound and careful work.

The memoir which stands first in the book gives an interesting account of the areas of sea-bottom in the Bay of Kiel known as "weisser" or "todter Grund." They are called "dead" by the fishermen because no fish are found on them, a fact probably due to the presence of sulphuretted hydrogen. The white felting which gives the name "white" is formed by threads of different species of Beggiatoa, a thread-like fungus classed with the Schizomycetes by Zopf and others who have stated that bacteria forms constitute a stage of their life-cycle. Thus *Monas Okenii*, *Bacterium sulphuratum*, *Clathrocystis rosea persicina*, and *Beggiatoa rosea-persicina* have all been described as stages of a single life-history. Dr. Engler is extremely cautious on this point, and limits himself to what he has seen. He does not agree with Warming that *Monas Mülleri*, which occurs with the Beggiatoæ, is the young stage of one of them; although he has observed one species sending off motile spherical spores. Two new genera of thread-shaped fungi are described which were found on a *Gammarus locusta* living on the white bottom. The paper is illustrated by a number of admirably executed drawings.

Thus the volume forms a very considerable contribution to the accurate scientific knowledge of the Baltic, for the attainment of which the Commission was instituted. Like all the other work published by the Commission, it exemplifies in the most convincing manner the truth that, to obtain light on marine problems, what is required is not a mass of evidence from people all equally without knowledge on the subject, but continued and elaborate research.

MASCART AND JOUBERT'S "ELECTRICITY AND MAGNETISM"

Electricity and Magnetism. By E. Mascart and J. Joubert. Translated by E. Atkinson. Vol. I. (London: Thos. de la Rue and Co., 1883.)

WE took occasion some time ago to draw the attention of the readers of NATURE to the "Leçons sur l'Électricité et le Magnétisme," by Professors Mascart and Joubert; we have now to thank Prof. Atkinson for an English translation of this valuable work. This is not the place to inquire into the necessity for an English translation of *any French* scientific work, not to speak of one which makes such demands on the culture of its readers as this does. It is enough for us to know that the publishers and translator consider the number of semi-educated Englishmen sufficiently great to justify their venture; it is our part to speak to the merits of the work and the manner of the translation.

The alterations in the matter of the book are so slight as to call for no remark. Our first duty therefore reduces itself to a simple iteration of our high opinion of its value as a scientific manual. At the present time the public is well supplied with scientific instructors. The good intentions of all of them need not be doubted; but the inactivity or modesty of some and the incompetency of others have brought it about that there are large gaps in our repertory of science text-books either not filled at all or filled very unworthily. It would not be accurate to say that vol. i. of the treatise of MM. Mascart and Joubert fills the greatest of these gaps in the department of electricity and magnetism; nevertheless it fills a place not at present wholly occupied by any English text-book of merit. It has the misfortune, no doubt, of overlapping to a large extent the great work of Maxwell; but we believe that the tyro in the mathematical theories of electricity and magnetism will find it of the greatest advantage to use Mascart and Joubert as companion and commentary to Maxwell's volumes. In all that relates to fundamental points and general theory Maxwell should be studied, even where he is hardest to follow, because his work was written, not to evade, but to meet, difficulties. On the other hand, Mascart and Joubert will be found invaluable in matters of detail. We know of no text-book in any language that contains such an abundance of elementary illustrations of electrical and magnetic theory, all arranged with an elegance peculiarly French.

The English version now before us is neatly printed and solidly got up. The translation on the whole is very well done. It would be easy to pick out small inaccuracies here and there, particularly in the early chapter. For some of these the translator is not altogether to blame; for the introductory part of the work seems to us to be less clear and carefully written than the following chapters, where the authors enter more into detail; and in that part of the book the translation leaves little to be desired. We noticed very few misprints, but one calls for correction: the name of van Troostwyk's collaborateur in the decomposition of water by the voltaic current was Deimann and not Diemann. No doubt this mistake occurs in the original; but the individual in question, though perhaps not widely known, yet deserved better than to be made quite unrecognisable. This brings to mind the only complaint of any gravity we have to bring against the editor of the English translation. Why did he not do something to remedy the one serious defect of MM. Mascart and Joubert's text-book, viz. the want of sufficient references to original sources of information? It must be remembered that the scientific student who goes the length of MM. Mascart and Joubert's leading strings is expected one day to walk alone; and some indication should be given him of the paths that lead to farther knowledge. A defect of the kind might be overlooked in a school primer, written to enable the oppressed schoolmaster to screw a Government grant on the minimum qualification from some reluctant inspector, but is to be deplored in a work of the present pretensions.

Instead however of complaining farther of what MM. Mascart, Joubert, and Atkinson *have not* done (perhaps had not the leisure to do) for us, it will be more fitting to conclude by thanking them heartily for what they *have* done, and done so well.

G. C.

OUR BOOK SHELF

Energy in Nature. By William Lant Carpenter, B.A., B.Sc. (London, Paris, and New York: Cassell and Co.)

THIS book is, with some additions, the substance of a course of six lectures on the Forces of Nature, and their mutual relations, delivered under the auspices of the Gilchrist Educational Trust.

It is of the greatest importance that the general body of the people, and more especially the intelligent artisan class, should become acquainted with the leading principles of the science of energy. The series of lectures delivered with this object represents one of the best sustained efforts to bring this great subject before the minds of this class of the people, and in collecting together and publishing these lectures the author has done a work which must be regarded as a scientific boon to the artisan.

In one respect this task has presented difficulties of a peculiar nature, due to the fact that our country has taken a leading part in developing the principles of energy—this science has in fact grown here, and the terminology has grown with it. At the present moment there is no man of science who speaks of the forces when he means the energies of nature, but there is a lagging behind in this respect amongst the body of the people, to whom the word force is a familiar one, and the word energy, in a scientific sense, very much the reverse. Accordingly one of the first duties of the author has been to define the exact relations between force and energy in a way suitable to his audience—a task which he has successfully achieved.

While in respect of importance the science of energy holds a paramount place, it is also a subject which lends itself admirably to the mode of treatment adopted by the author of this volume. Probably no subject is more difficult of conception on general principles merely, and without reference to the actualities of life. The philosopher in his study may have but a vague conception of these general laws, and his assent to the definition of work may be purely intellectual. Perhaps he may never have witnessed a well marked case of the transmutation of energy, nor may he have the consciousness that he himself is frequently the subject of such transmutations. The artisan is, however, in a totally different position. After a day's hard toil he is well able to realise in a very vivid manner the meaning of the word *work*. To spend his personal physical energy, and to recruit it by food, are operations in which he is constantly and consciously engaged. Hence it follows that a theory which borrows all these facts as illustrations of its truth appeals to the artisan in a much more emphatic way than it does to the mere student of science. To use the scientific terminology, the latter may have more *kinetic* intellectuality than the former, but the artisan is in a *position of advantage* which enables him to grasp the truths of the science. A book, therefore, which, like the present, abounds in good illustrations and in clear and simple statements, carrying practical applications, is one peculiarly fitted to a class better qualified by education and experience to perceive the concrete than to appreciate abstract general principles.

B. S.

Journal of the Royal Agricultural Society. Second Series, Part II. Vol. XIX. October, 1883. Price 6*s*. (London: John Murray.)

THE current number of the *Journal of the Royal Agricultural Society* has just reached us. It fully maintains the reputation so justly earned by previous numbers, and contains papers on many topics of present interest to agriculturists. Among the principal of these may be mentioned "The Progress of Fruit-Farming," by Mr. Whitehead, of Barming House, Kent, himself largely interested in this business. The continued reports upon Prize Farms are worthy of attention as showing what is being done on the best farms in various districts. A report on sheep-feeding experiments conducted at Woburn by Dr. Voelcker in his capacity of chemist to the Society, and a report on wheat mildew, by Mr. W. C. Little, of Stag's Holl, form the chief attractions to practical farmers. Among the more purely scientific or speculative contents may be mentioned a contribution from Rothamsted, by Sir John Lawes and his able coadjutor, Dr. Gilbert, upon the composition of drainage water collected at Rothamsted, and a valuable paper upon nitrogen as nitric acid in the soils and subsoils of certain fields on the same estate. The remainder of the volume is chiefly occupied with useful official matter, such as the Weather Report; the Botanical Report, by Mr. Carruthers; and Reports on Live Stock, Implements, &c., exhibited at York. A touching tribute is paid to the memory of a late president of the Society, the late Lord Vernon, by Mr. Wells, himself an ex-president. Perhaps the most striking and instructive paper is that by Mr. Thomas Bell upon the Yorkshire Prize Competition, containing a full report of the Tuyers Wood and East Park Farms, occupied by Mr. Turnbull. In these days, when dairying is justly attracting very special attention, it is highly interesting to receive sound information as to the methods used on thoroughly well-managed farms. A daily record of the milk yielded by each cow in a dairy containing 100 animals in milk is in itself highly useful, and worthy of imitation. It is impossible in a short notice like the present to open up the various topics dealt with. It has ever been the wise policy of the "Royal Agriculturist" to fill its pages with contributions from specialists upon their own specialities. There is no padding or superfluous discursiveness, and sometimes to the uninitiated there may appear to be a want of that introductory and explanatory matter which entices on the general reader. As a record of agricultural research and progress, the journal holds a high position, which the number just issued fully maintains.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On Chepstow Railway Bridge, with General Remarks suggested by that Structure

IN a letter to NATURE of some months past, suggested by a special subject of engineering, I pointed out the necessity of clearly understanding the effects of endwise pressure on metallic columns, in respect of its tendency to cause springing or buckling of the columns. I remarked that there is a total want of experiments on the subject (Mr. Hodgkinson's observations, made on a very small scale, being excepted), and I gave some details of a theory by which the effective arrangement of such experiments might perhaps be facilitated. I have lately observed in an engineering work a failure of a different class arising from endwise pressure, of a kind which I had not anticipated, and which appears to be perhaps more dangerous than even the buckling to which I had called attention.

In the neighbourhood of Chepstow, the River Wye is crossed by a railway bridge of a single span. The four corners of the bridge are supported by iron tubular vertical, columns of considerable length. One of these columns (on the Monmouthshire side of the river, and on the lower side of the bridge as regards the course of the river) is split, with several important longitudinal fissures. To avert the present destruction of the bridge, strong iron hoops have been placed surrounding this tube, drawn tight by screws and nuts, exhibiting a somewhat unsightly appearance.

For clear understanding of this state, the reader may figure to himself a cask or barrel, set on its end, and loaded on the top till its staves burst outwards; then he must conceive a hoop to be placed round the body of the cask, and drawn till the edges of the staves are wholly or nearly in contact.

I do not doubt that this column is now safe. But there are other columns supporting the bridge which are exposed to the same dangers: the bridge is heavy, the loads from the Taff and the Tawe are not light, and the jar of ponderous locomotives may try every original weak point or may create new ones; and I think it would be well provisionally to encircle the other supporting columns in the same way as the one which has failed.

A symmetrical system of rings, with some attention to simple elegance, would remove the offensive effect produced by the bent bars of mere blacksmith's work which now surround a single column.

But it is not specially to the state of the Chepstow Bridge that I wish to call the attention of the public. It is to the total want of practical knowledge as to the enduring power of metals, with which this bridge was built, and with which other such bridges must at present be built. We are totally without experiment on the danger of springing or buckling, and on the danger of bursting (now, I believe, for the first time brought forward). And we might perhaps consider such experiments as well falling within the province of those organised bodies whose union is based on the promotion of the most important determinations in civil engineering.

The Institution of Civil Engineers (with which body I have a much-valued honorary connection) has lately departed in some measure from the strict subject of engineering to which its attention had been successfully given for so many years. I venture to suggest that this body might well take up the conduct of experiments bearing on engineering. The examination of the effects of force in mere crushing of external surfaces has been admirably prosecuted by American engineers. But the examination of bending and bursting, as the effects of end-pressure, is still open to the engineers of Britain. The funds of the Institution appear to be amply sufficient for such purposes, and the undertaking of them would undoubtedly be considered as honourable to the body. G. B. AIRY

The White House, Greenwich, November 17

Physiology in Oxford

A PARAGRAPH appeared in the *Spectator* of Saturday, the 10th inst., on the Oxford memorial concerning the University Physiological Laboratory. That part of it which affects Magdalen College appears to me to rest upon erroneous information, and is certainly calculated to spread an entirely false and misleading impression of the attitude of this College in the matter, and of the University in general.

If you will allow me to quote the paragraph, and at the same time give you the actual facts, I think you will easily form an opinion on the real state of the case.

The paragraph states that the signatures were received "from members in Oxford and its suburbs, and the rest from a circle of about fifteen miles round."

The fact is that the signatures are not drawn exclusively from either the smaller or even the larger area, one of the so-called Magdalen signatures being that of a member of the Hereford Cathedral choir.

The paragraph goes on to say :—"We are told that Magdalen men have signed it more numerously than any other College but one, and, in proportion to the size of the College, more numerously than any. Now, as Prof. Burdon Sanderson is *ex officio* a Fellow of Magdalen, and as Magdalen has for years past had a physiological laboratory of its own, this popularity of the memorial among Magdalen men is highly significant."

On this I have to remark that the signatures are representative neither of the governing body of the College, nor of its resident members.

The governing body of the College consists of the President and twenty-four Fellows ; of these twenty-five *three alone have signed the memorial.* The resident members, as shown by the list of congregation, number twenty-two ; of these twenty-two *only six* have signed.

Finally, as regards the last paragraph, it is true that Magdalen College has for years past had a physiological laboratory of its own, and it is further true that the University teaching of physiology has been carried on there, previous to the advent of Dr. Burdon Sanderson, for years past under a Government licence with the full and express consent of the whole governing body of the College, a fact which is indeed significant, but hardly in the way in which the *Spectator* appears to have been informed. EDWARD CHAPMAN

Magdalen College, Oxford, November 15

Green Sunlight

MR. G. H. HOPKINS' observation that the parting ray at sunset is sometimes brilliant emerald-green brings to my memory a somewhat similar experience. On September 13, 1865, watching on the summit of the Rigi for sunrise, I caught the very first possible glimpse of the sun's disk as, on a very clear morning, he emerged from behind the sharply-defined outline of a distant mountain. The very first rays, although necessarily proceeding from the comparatively obscure limb of the sun, were dazzlingly brilliant, and of a superb emerald green colour. But almost instantly, as more of the sun appeared and his light grew sensibly more intense, the green passed away or was merged in the yellowish white of ordinary sunlight.

In my case I do not doubt the phenomenon was purely subjective, for before sunrise the sky was all lit up of a magnificent crimson hue. Every one must have noted how the moon when surrounded with bright crimson clouds looks more or less decidedly green.

A very striking effect of this sort, like the others an example of the well-known visual phenomenon of "accidental colours," may be artificially obtained, any time the moon shines, by burning an ordinary "blue" signal light. After my eye had been intensely excited by such a light close at hand, I have seen the moon, near or at its full, of a deep plum colour, by which I mean the colour of the bloom on a black plum or on a well coloured Hamburg grape. Or, in place of these, the *violet* of my friend Prof. Piazzi Smyth's exquisite chart of colours in his "Madeira Spectroscopic," or the *bleu violet* of Chevreul's chromatic circle. I recommend the experiment as easy of performance and exceedingly beautiful in its effects. Possibly a small blue light would suffice. But, on the occasion to which I have referred, certainly not less than thirty ounces of nitre, ten of sulphur, and five of black antimony sulphide were employed. These, mixed in fine powder, may be burned in a case about six inches high and four in diameter ; of course in the open air, and where no mischief may accrue from an intensely hot and voluminous flame.

In a communication made to the Royal Society of Edinburgh in 1852 (*Trans.* vol. xx. pp. 445-471), I adduced evidence to prove that a continuous thin layer surrounds the sun's photosphere, of which upturned portions form the red protuberances seen at total solar eclipses ; and I then showed that if the well known darkening of the sun's limb be due to absorption in his atmosphere, it can only be caused by such a *thin* envelope. The existence of this envelope, the sun's chromosphere, is now fully established. If, from the red colour of its upper portions, we may infer the resultant tint emitted by the whole to be red, then, by a well known law, the discolouration of the sun's limb due to its absorption should be of a greenish hue. But such an effect would necessarily be but slight, and could not explain the brilliant green witnessed on the Rigi. Nor do I recollect any instance where the first emerging rays of the photosphere at the end of a total eclipse have been observed to be green.

WILLIAM SWAN

Ardchapel, Dumbartonshire, November 8

A LETTER from Barinas, Venezuela, states that on September 2, from daylight until noon, and from 3 p.m. to sundown, the sun appeared like a globe of burnished silver. Between noon and three o'clock it was of a bluish-green colour. This appearance in the western hemisphere seems to dispose of the suggestion of the Java eruptions as the cause of green suns in India.

HYDE CLARKE

Mangrove as a Destructive Agent

As I have never seen the mangrove mentioned but as a conservative or productive agent as regards geological change, it may be interesting to readers of NATURE to hear of its acting in a contrary direction.

In several parts of eastern tropical Africa, where the shores are mostly of upraised coral limestone, I have noticed the effect of mangrove in eating away this rock, but nowhere have I seen it so well marked as in the Island of Aldabra, some two hundred miles to the north-west of Madagascar, and which I surveyed in 1878.

Aldabra is an upraised atoll about twenty-two miles long, and presents low cliffs of about fifteen to twenty feet of solid coral rock to the sea and also to the lagoon, which is, at low water, nearly dry

The mangrove has established itself on the edges of the lagoon, doubtless from seed transported by the currents, and, in all places where it has done so, tortuous creeks or little gorges run back into the coral, filled with mangrove trees (standing in deep mud of the adhesive and fœtid nature so characteristic of mangrove swamps), which stretch out their roots to the coral walls around them, and, as it seemed indubitably to me, in some way decompose the softer parts and eat their way in. The island is riddled with these creeks, always filled with mangrove, and opening into the lagoon.

The outer face of the island is of course being slowly undermined by the sea at high water, presenting overhanging cliffs impossible to scale, and the island is wearing away from that cause also, but the destruction from the mangrove is much more important, and at no very distant period, as it seemed to me, the upraised island will be again reduced to its original level as an ordinary atoll.

It would be interesting to know how long the mangrove has been there, for as Aldabra is one of the two oceanic groups in which the giant tortoises still exist indigenous, it must have been in its present condition of upraised atoll, I imagine, for a long period. It could never have been much larger in diameter, from the soundings round it, but the mangrove may have greatly increased the size of the lagoon by steady working at the inner rim of the islands, the actual area of which is now but small, from their narrowness.

I may mention that the island is covered with low, tangled scrub, which has managed to find foothold and sustenance on the rock, for there is but little or no soil, and the top of the rock is everywhere cut up by sub-aërial action into the sharp, honeycombed, and jagged surface which upraised coral in the tropics, uncovered by grasses, soil, &c., always wears into, and which, by the way, makes it extremely difficult to walk over, a difficulty much increased in this instance by these mangrove channels, as well as the tough nature of the matted, thorny bushes. A walk in Aldabra is the most aggravating and slowest piece of locomotion I have ever engaged in: and nothing short of the patience, perseverance, and general disregard of time of the tortoise tribe can make it an agreeable residence. Some of my negro sailors were sent into the bush to hunt for tortoises, and after three days' search brought back one, which is now in the Gardens of the Zoological Society; but they returned nearly as guiltless of artificial clothing as their captive.

The "Cloud-Glow" of November 9

THE beautiful after-glow of Friday, the 9th instant, was most striking as seen from the west side of Hampstead Hill, where its first development was made more effective by a frame of dark cumulus, with a fringe of dusky green tint, carried up from the sunset quarter by a westerly breeze, rather rolled up like a curtain, exhibiting the richly-coloured scene behind as it was withdrawn. I estimated the altitude of the upper edge of the glow at about 30°; but at Freshwater, Isle of Wight, it has been described as extending nearly to the zenith. There would be no difficulty in calculating approximately the height of the cirrus—as desired by Mr. Russell—if it could be assumed that the reflection was from the same matter in both cases, which is improbable.

J. J. WALKER

Waking Impressions

A CURIOUS case I have just read in a recent number of NATURE recalls a somewhat similar experience of my own, rather earlier in date. I awoke in the middle of a story told by an internal voice—a voice felt, not heard. I listened with curiosity and interest, as totally unprepared for what was coming as if the narrator had been Gladstone or Ruskin. I believe when I awoke I had a dim recollection of what had gone before, but I strove afterwards in vain to recall it. All I know of the history of the mysterious lady is the following fragment: "She had many admirers, but she gave the preference to Tom, because he promised to marry her in the West Indian fashion. He drew her three times through a hoop, once standing, once sitting, once lying, which signified that he would never desert her in youth, maturity, or old age."

I have not the least idea who "she" was. I know no one I call Tom except an old schoolfellow long married, and, to the best of my belief, I never heard of such a custom in the West Indies or elsewhere. Once since I have waked in the middle of a dream which went on, but it was a dream of a very commonplace character.

Barytes from Chirbury

I AM indebted to Mr. Yelland of Wotherton for sending me some fine examples of the crystals described by Mr. Miers in NATURE, vol xxix. p. 29, and am collecting several particulars respecting their occurrence. Some time ago I commenced a determination of the faces, but my work has been interrupted.

The characteristic plane E is mentioned by Carl Urba (Groth, *Zeitschrift für Crystallographie*, v. 433, 1881) as occurring on barytes crystals from Swoszawice in Galizien. In a measurement I made last year to determine this plane on one of the Wotherton specimens I obtained E E′ as 39° 59′, and, using Miller's distance for *b d* leads to the symbol 412, and by calculation the distance *a* E as 26° 2′. Carl Urba gives its calculated distance as 26° 4′, and measured distance as 25° 58′.

"Salt Rain and Dew"

LOOKING over the "School Geography" of Dr. Clyde (Edinburgh, 1870), I find, on page 32, in the paragraph headed "Russian Lakes," the following remarkable statement:—"In the south-east region, not only the lakes, *but the very rain and dew likewise are salt*, a phenomenon common to all the shores of the Caspian and Sea of Aral" (the italics are mine). Will some one of your readers kindly refer me to the traveller's tale in which this myth originated.

Esterel, Temple Road, Dublin, November 17

AN INDIAN WEATHER FORECAST

THE period of drought in Upper India, which happily came to an end in the latter part of August, was not entirely unforeseen, as will be shown by the following extracts from the Government *Gazette*; and the facts will probably be not without interest to meteorologists in Europe and elsewhere.

Extract from the "Gazette of India" of June 2, 1883

"That the unusually dry weather now prevailing over the North-Western Himalaya, and that which, though less abnormal, characterises the whole of North-Western India at the present time, is an effect of the unusual accumulation of snow, is a conclusion justified by the experience of the last few years; and were it not that the snow is rapidly decreasing under the unobstructed radiation of the sun, there might be some reason, judging from the present limited experience, to anticipate some retardation of the rains of the Upper Provinces, and possibly even in Western India generally. But, on the other hand, the fact that, during the months of April and May, the atmospheric pressure over the greater part of the country has been below the normal average of the season, is one which, arguing from the same experience, portends favourably for the timely influx of the monsoon. In Bengal it may be said that the present prospects are wholly favourable.

(Signed) "HENRY F. BLANFORD,
Meteorological Reporter to the
Government of India

"Simla, May 18, 1883"

"Since the above was written, there has been heavy rain for many days on the outer hills, and more or less on the plains of the Punjab, and apparently a very heavy fall of snow on the higher ranges. At the present time, as seen from Simla, the latter are white with snow, down to a level of about 11,000 or 12,000 feet. And some 500 feet of the top of the Chor (11,982 feet) is also covered with a snow-cap. If, therefore, the mountains of Lalwul, Spiti, and other more distant ranges have shared this fall, if it is as extensive as it is apparently heavy on the visible ranges, and if the views which the experience of recent years seems to justify, viz. that an unusual extent and thickness of snow on the Himalaya is productive of dry north-west and west winds in North-Western India, are valid, we must be prepared for a long spell of dry weather and a retarded rainfall in the Upper Provinces. The present season will serve as a test of the validity of the above view.

(Signed) "HENRY F. BLANFORD,
Meteorological Reporter to the
Government of India
"Simla, May 31, 1883"

Information was subsequently received to the effect that the heavy snow of the winter months as well as that which fell at the end of May was restricted to the outer range. In the interior of Lalwul and Spiti and in the Pangi valley the snowfall was very deficient. Nevertheless the May fall on the outer range seems to have sufficed to produce the effect predicted.

Extracts from a Memorandum on the Chief Weather Characteristics of the Month of June, 1883, *in India, in the "Gazette of India"*

"In Bengal, after some weeks of close cloudy weather, with occasional showers, the monsoon rains were ushered in on June 13, with a little cyclonic storm, formed apparently on the coast of the Sunderbuns. From the coast on the three following days this storm passed inland, on a north-west course, bringing heavy rain in its track, as far west as Behar, and a moderate fall up to Allahabad; beyond which, for a time, the rains did not advance. . . . At Bombay it blew strongly on the 11th, 12th, and 13th, but not from the monsoon quarter; and afterwards the wind fell light, and so continued till the 24th, when the monsoon set in steadily. But the rainfall has been light throughout the month, and, at its close, was six inches short of the normal average. On the 26th or 27th a second cyclone was formed at the head of the Bay of Bengal, causing heavy rain around the coasts, and especially those of Orissa and Ganjam; then, travelling westward, the centre reached Cuttack on June 30; Seoni on July 1; Indore on the 2nd; and lay between Kurrachee and Rajkot on the 3rd. It caused very heavy rain in Gujerat, flooding the rivers, and interrupting railway communication between Bombay and Baroda.

"In the North-Western Provinces, with the exception already mentioned, the rains did not set in before the 26th, but throughout the month the wind was, in general, easterly, and occasional thunderstorms occurred. In the Punjab also, the first rain fell between the 26th and 29th, but in the eastern half of the province the prevailing high temperature was mitigated by an occasional dust-storm. . . .

"In Lower Bengal rain of importance fell on twenty-two days. The total fall of the month was five inches in excess. . . .

"In Rajputana, Sind, &c., the number of days on which rain fell was only four, and the average total was less by three-quarters of an inch than even the small amount which generally falls in this region in the month of June. . . .

"From the above it appears that, over a large tract of country, the monsoon so far has been weak. On May 28 it was reported to have burst at Cochin; and between that date and June 5 it appears to have spread along that coast as far north as Goa. In Bombay itself the weather has been showery, but there have been no very heavy falls of rain. On the Bengal side, on the contrary, the south and south-west winds have brought up even more than the normal amount of rain, and the weather at the head of the Bay has been somewhat exceptionally rough In Northern India the monsoon current has been much delayed, and in parts of the North-Western Provinces and the Punjab continuous rain has hardly yet set in.

(Signed) "W. L. DALLAS,
Assistant Meteorological Reporter
to the Government of India"

Extracts from a Memorandum on the Chief Weather Characteristics of July, 1883, *in India, in the "Gazette of India"*

"Except in the North-Western and at a few Central stations, the rainfall of the month shows on the whole comparatively little departure from the average.

"After the disappearance of the storm noticed in the June summary, which passed from the Bay of Bengal across India, &c., . . . there occurred a general rise of the barometer, a corresponding decrease in the humidity of the atmosphere, and a cessation of the rainfall, over a large tract of country for two or three days. On the 5th or 6th, however, rain recommenced generally and continued for some time. In the eastern half of the North-Western Provinces, Assam, Bengal, Burmah, and the south of the peninsula, it fell more or less on every day, till the close of the month, but over Western and North-Western India the fall ceased about the 19th, and from that date till the end of the month a decided break in the rains occurred, and fine weather set in.

"On the plains of the Punjab there were only eleven wet days; the break in the rains, which commenced on the 19th, being very decided in this province. In consequence the amount of rain for the month, and, except in the Indus valley, the total since June 1, was several inches below the average. . . .

"The weather in the western half of the North-Western Provinces was similar to that experienced in the Punjab, but in the eastern half it was wetter, the number of rainy days being nineteen. In the Meerut division five inches less than the average amount fell during the month; while at Lucknow eight inches and at Allahabad one and a half inches more than the average was registered. . . .

"In Lower Bengal and parts of Behar the rainfall was several inches above the July average; while in Purneah, Patna, and Orissa it was deficient. The average number of wet days was twenty-six, and no break in the rains of any consequence occurred within these provinces. . . .

"In Rajputana the rainfall was about the average amount, and occurred on thirteen days; scarcely any fell after the 17th. . . .

(Signed) "W. L. DALLAS,
Assistant Meteorological Reporter
to the Government of India"

Extract from a Memorandum of the Chief Weather Characteristics of August, 1883, *in the "Gazette of India"*

"The month just elapsed was one of very deficient rainfall throughout India, except in the provinces of Madras, Berar, and Assam. The break in the rains, which during the latter half of July was very general in North-Western and parts of Central India, became even more pronounced throughout that region during the first three weeks of the month under review; and extended, though in a modified degree, to Behar and a large part of Bombay. The drought was apparently at its height, both as regards extent and intensity, during the second week in August. . . . On the 19th, however, a change commenced. The air became slowly damper over the Central and North-Western Provinces, and the sky more cloudy; and very gradually these changes spread, till at the close of the month rain had extended to the Punjab, Rajputana, and Gujerat; in Rajputana and a large part of the Punjab and the North-Western Provinces it was only on the last two days of the month that rain began to fall, and even then in small amounts. . . .

(Signed) "W. L. DALLAS,
Assistant Meteorological Reporter
to the Government of India"

The above extracts speak for themselves. The results do not accord precisely with the terms of the prediction, inasmuch as the rains, instead of being simply retarded, penetrated for about a fortnight to the Upper Provinces, and then gave place to the dry north-west winds, which are characteristic of periods of drought. But there is no reason to regard the snows as inactive during this rainy interval. At Simla this rainy period was one of frequent thunderstorms and on more than one occasion of hail,[1] and in fine intervals the existence overhead of the ominous north-west wind was established by the steady drift of the higher clouds (*cirro-cumulus*, &c.). The outflow of dense air from the snow-fields was therefore active, although it was only at a later period that it descended to the level of the lower hills; and then, chiefly as the result of diurnal convection, to the plains of North-Western India.

The full discussion of the evidence for the dependence of dry winds on the snowfall will be undertaken elsewhere. It must not, however, be supposed that the Himalayan snows are to be regarded as the *sole* cause of drought. Causes of wider incidence are sometimes in operation. Thus, in 1876 and 1877, an unusually high atmospheric pressure prevailed over nearly the whole of Asia and Australia. Whether there was any unusual accumulation of snow on the vast mountain tracts of Central Asia or over the northern plains in those years would be an interesting subject of inquiry were the means of information forthcoming. H. F. B.

NORDENSKJÖLD'S GREENLAND EXPEDITION[2]

III.

WE give a few extracts from Baron Nordenskjöld's concluding letters on his journey down the west coast of Greenland and his visit to the east coast:—

At Ivigtut a visit was made to a valley which, on account of its copious flora, has been named Grönnedal (Green valley), and another to the spot where the inland ice falls into the Arsukfjord. In the former place Dr. Nathorst found, in a kind of syenite, a blue mineral which seems to be sodalite. This discovery is chiefly remarkable from the circumstance that this mineral is also found in the vicinity of the small kryolite deposit at the Ilmen mountain in the Ural, which seems to indicate that a kind of relation exists between these two minerals, both strong in natron, which circumstance may be of service to the geologist in search of kryolite. From the excursion to Grönnedal Herr Kolthoff brought with him some rare butterflies and other insects, while of the botanical finds there were splendid specimens in bloom of *Linnœa borealis*, which is quite plentiful about Ivigtut. It has not before been known to exist in Greenland. The zoologists found only three kinds of land mollusks, viz. a physa, a vitrina, and a helix, which were all few in number. The entomological harvest consisted of a few beetles, butterflies, and insects of other kinds.

On their way to Julianehaab, as they steamed down the narrow fjord in pitch darkness and a perfect calm, "we saw suddenly behind the vessel on the surface of the sea a broad but clearly defined band of light. It shone with a steady, yellowish light, somewhat like that of phosphorescent elements, while, in spite of the speed maintained, viz. four to six knots, the band came nearer and nearer. When it reached the ship it seemed as if we were steaming through a sea of fire or molten metal. After a while the light travelled beyond the vessel, and we saw it at last disappear on the horizon. Unfortunately I had not an opportunity of examining it with the spectroscope. It was beyond doubt of a different nature to the bluish-white phosphorescent light, which throughout its appearance was seen distinctly in our wake, and as the light was perfectly steady it cannot have been caused by the phosphorescence from a passing shoal of fish. A shoal of fish would have occasioned some stir in the sea, but in this case the surface was calm throughout, while phosphorescence from the same would have been bluish in character, not yellow as this was. The Esquimaux stated that a glacier river in the vicinity shed a thin layer of brackish clay-water over the surface of the fjord, and fancied that this circumstance was in some way or another connected with this grand phenomenon, which they themselves had never before witnessed. There was at the time no aurora visible, the sky being covered with clouds. The cause of this remarkable phenomenon, which made the *Sophia* seem to steam through a sea of fire for fully fifteen minutes, I have been unable to ascertain; maybe it was a phenomenon such as this which made Lig-Lodin, of the Greenland Saga, relate to King Harald Sigurdson that he had once sailed over a spot where the sea was on fire."

At Fredriksdal Nordenskjöld engaged two Esquimaux to act as pilots in the sounds on the east coast, north of Cape Farewell. One of them stated that remains of buildings, which were not built by the Esquimaux, are to be found in nearly every great fjord on the east coast, particularly in the large ones of Umanak, Ekaleumiut, and Igdluluarsiut. Entire walls do not remain standing, but though low they are extensive. The largest ruin is said to exist at Igdluluarsiut. A fine kind of soft stone is to be found on an island south of Umanak, from which pots were made to three feet in diameter. This mineral deposit is of special interest in reference to the ethnography of Greenland, as the Umanak fjord is situated in lat. 63°. This name is, however, a common one for places among the natives. Ivar Baardsen, in his famous description of Greenland, states that a soft stone was found on Renö, outside the Einafjord, from which the largest vessels were made. Cannot the mineral deposit at Umanak be identical with this? These statements, as well as others received from the "Eastlanders," and the remarkable Norse characteristics possessed by the same, which the missionary Hans Egede pointed out long ago, seem to Baron Nordenskjöld to refute the theory now mostly advanced as to the Norse colonies, viz. that they were situated on the south-west coast of Greenland.

In spite of predictions of failure and even disaster before he left Europe, Nordenskjöld decided to attempt to land on the east coast, south of the Arctic circle. After some difficulty they succeeded in anchoring in the Kangerlutsiok Bay, but on account of the state of the ice they had to stand to sea again, and steamed along the ice-belt lining the coast, in order to find an opening by which the shore might be reached. The fauna of the sea here was very poor, and they only saw in two days one whale, a few seals, and a very small number of sea birds. The abundant fauna of the coasts of Spitzbergen and Novaya Zemlya is thus entirely wanting on the east coast of Greenland. The cause of this may be the great depth of the sea right up to the shore, which prevents the animals from fetching their food from the bottom; perhaps also the war of extirpation which the natives seem to have carried on for years has also contributed thereto. The auk and the *Uria grylle* are, however, said to breed in large numbers on the rocks off Cape Farewell. The Esquimaux pilot stated that he had been told by old people that they could remember the *Alka impennis* having been found here. The natives called it Isarokitsok. Only a little distance out to sea they found a warm current—rising to 6° C.—coming from the south. The drift-ice was what Arctic skippers call "knatteris," *i.e.* little bits, viz. remains of large floes after the influence of the summer heat and the Gulf Stream. Very few icebergs were seen, and they appear to be far more numerous on the west coast. As it was now late in the season, and the coals were nearly done, Nordenskjöld had reluctantly to renounce the plan of reaching the fjords where the greatest ruins are said to exist, and, instead, attempt to reach the south shore by Cape Dan, a promontory which, if the Einafjord was situated at Umanak or Ekaleumiut, should be the Herjolf's Naze of the Sagas. "On the 4th, when off the Cape, we met the ice twenty miles from the coast, which was, however, passable, as it consisted mostly of large, loose floes only a few feet above water, while nearer the shore it again became heavier. Beyond this we saw an ice-free channel three to four miles wide. The sea was as smooth as a pond, and a boat could easily reach the shore. The mountains ran mostly into the sea with almost perpendicular declivities, without any grass-covered underland. Opposite us we saw a small bay, into which I steamed, in order to take the sun; but finding both the depth and the bottom unsuitable for anchoring, we only landed for a few hours, while some of the crew went on the hills above to look for a better harbour. The staff returned on board with a rich harvest from the steep slopes, the flora of which was copious beyond expectation. The sailors reporting a harbour near, I steamed thereto and cast anchor. It was a beautiful fjord, with several arms, which was only connected with the sea through a small opening, and was well sheltered. It was the first harbour on the east coast south of the Polar circle, in which a vessel had anchored for several centuries.[1] It was named 'King Oscar's Harbour.' If Cape Dan is the old Herjolf's Naze, this harbour is the "Sand" described by Ivar Baardsen, 'much frequented by the Norwegians and traders.' That the Norwegians had once been here was demonstrated by walls of loose stones erected on the mountains above the harbour, which had, no doubt, served as landmarks for finding the almost hidden opening of the fjord. We found, besides, some stone ruins of a smaller house, identical with those found on the west coast. These ruins are, of course, not extensive enough to demonstrate that here was situated one of the 'Bygder' (parishes) of Greenland, but they may certainly serve as sign posts for future explorers of the east coast. As soon as at anchor we went on shore, and spread in all directions in order to examine the neighbourhood. King Oscar's Harbour is surrounded by soft, close, grass slopes and flourishing shrubs. The fauna appeared to me more copious and the grass less mixed with moss than on the west coast in the same latitude. In one of the valleys a river flowed, the shores of which consisted of loose sand without any covering of grass. Here were found traces of the Esquimaux. Some of the footprints were days old, but others were so fresh that the moist sand had not had time to dry. Most probably they had taken flight on seeing the steamer forcing the barrier which had hitherto formed their shelter. We found plenty of remains of them in the shape of huts, graves, fox-pits, &c. The naturalists gathered here a quantity of fresh materials of the fauna and flora of East Greenland, among which I may specially mention the well-known *Potentilla anserina*, which is found so often near the Norse ruins in West Greenland, and which may, for that reason, be a sign of the Norse colonisation of East Greenland. We found traces of reindeer, but none of the musk-ox; neither did we see any bears or walruses, and only a few seals. Our whole bag was two ptarmigans. That the Esquimaux had decamped was very annoying, as they could no doubt have given some valuable information relating to this part of Greenland and the tribes which inhabit it."

---

[1] These accompaniments are characteristic of the spring rainfall both on the hills and the plains, not of the monsoon rains, and indicate demonstrably in most cases the existence of a dry upper current.

[2] Continued from p. 42.

After reconnoitring the coast still further, Baron Nordenskjöld decided that his best course was to return at once to Reikjavik. Before doing so, however, some hours were spent in dredging and in hydrographical research, as well as in photographing some of the coast scenery.

"Having thus given an account of the work of my expedition, I have to point out that we have been the first to penetrate into the heart of Greenland, and that our journey has resulted in learning something about this continent, the natural conditions of which may probably give us a clue to the true condition of Scandinavia during the Glacial period, the study of which is therefore of such great importance to the geology of North Europe. Besides this, valuable scientific data have been collected during my voyage along the east coast of the composition of the ice-belt which bars the way *from the east* to the southern part of Greenland, while many errors as to the state of the east coast of Greenland have been corrected. In addition to these objects one more has been attained, viz. the anchoring of a vessel by the shore of East Greenland, an achievement attempted in vain for centuries. If thus the work of the numerous expeditions despatched since the sixteenth century by sea to the part of Greenland lying opposite or south of Iceland to the part where the Norse Österbygd was or was not situated, it will be found that not one of them succeeded in reaching the coast.

"A few words more in conclusion as to the purely scientific results of the expedition. During the voyage of the *Sophia* along the coast of Greenland from Cape Dan past Cape Farewell to Cape York, and further from Cape York around Cape Farewell to Ingolf's Mountain, hydrographical researches and dredgings were effected whenever time and weather would permit. These labours were conducted by Herr Hamberg and Dr. Forsstrand. In addition, Herr Hamberg effected a number of analyses of sea water, and the gases contained therein, from various depths, while he brings home a series of the most carefully effected measurements of the temperature of the sea, which demonstrate that the *cold current* running along the east coast is, both in width and depth, very insignificant, and rests *even near the shore* upon one of warm water produced by the Gulf Stream. Davis Sound and Baffin's Bay, on the other hand, are filled with cold or very slightly warmed water *to the bottom*. Contrary, therefore, to the general belief, *the west coast of Greenland is washed by cold water, while a greatly heated current coming from the south runs along the east coast a distance of 40′ to 50′ only from the shore.* This current must exercise a great influence on the climate of the east coast, which may be more moist, but, I believe, not colder than that of the west coast.

"The dredgings have yielded Dr. Forsstrand a fine harvest of marine animals, &c., of which I may mention gigantic sponges from great depths in Denmark Sound (between Iceland and Greenland). The dredgings on the east coast were, however, greatly impeded through causes detailed above, and by the circumstance that the bottom consists mainly of huge boulders, which tore the net. Of the animal species existing on land or in fresh water, Herr Kolthoff has collected rich fresh materials of the Greenland fauna. Especially will the variety of insects collected be of great instructive value to science. On account of the limited accommodation on board, and from the circumstance that the flora of Greenland is well known through Danish and Swedish specialists, I took no botanist with me. But even in this field new materials have been gathered through the zeal given to such researches by Dr. Nathorst and Dr. Berlin whenever time permitted. The collections of microscopical plants which have been made, the true place of existence of which is the ice and the snow, must particularly be of great value. They are besides of additional interest to the expedition, as they belong to a new branch of science which has in the first instance been created by Swedish *savants*. The collections, perhaps, of most value to science have, however, been made by Dr. Nathorst from the North-West Greenland so-called basalt formation, which is remarkable for the quantity of fossil plants contained in the clay, sand, and tuff strata there. Of course some very fine palæontological collections have been brought from these parts before, especially by the Swedish expedition of 1870, and by some Danish ones under Dr. K. Steenstrup; but it is the first time that a palæontologist has visited this spot, and I am, in consequence, convinced that the objects gathered by Dr. Nathorst, when scientifically treated, will yield many new data on the copious flora which once covered the ice-laden regions round the Pole.

---

[1] North of the Polar circle the east coast of Greenland is in many places easily accessible.

"Finally, the expedition has brought home some splendid specimens of the remarkable minerals found at the well known deposits at Kangerdluarsuk and Ivigtut, while I have on the inland ice collected, as previously stated, a great many samples of the dust found on the ice, and which I have named kryokonite. I hope, when this has been exhaustively analysed, to be able to furnish fresh proofs in support of the theory that this deposit is, at all events partly, of cosmic origin, and thereby contribute further materials to the theory of the formation of the earth. Dr. Nathorst was, as previously stated, prevented by the ice from reaching Cape York and examining the blocks of ironstone lying there, but their existence has been corroborated beyond doubt by the Esquimaux in the neighbourhood. Here the expedition obtained some valuable ethnographical objects, and it learnt a fact from the natives which may be of considerable importance as to the question of the wanderings of the tribes around the Pole, viz. that four 'Russian Esquimaux' had come to Wolstenholme Sound. They said they were the last survivors of a tribe which had left their place of habitation by the Behring Strait (or the northern shore of Asia?) in search of a new place of settlement, and who had at last reached Smith's Sound. These are the results of my expedition to Greenland in the *Sophia*. The scientific collections made will be distributed among the museums of my country."

A. E. NORDENSKJÖLD

THE ROTHAMSTED GRASS EXPERIMENTS[1]

THERE is at Rothamsted nothing which will more impress the visitor than the seven acres of meadow land in the Park, the many years' experiments upon which with different manures constitute the subject of the above-named memoir. The twenty parallel plots into which the area is divided appeal at once and forcibly to the eye by the obvious differences in their herbage. A plot here with rich green grasses waving luxuriantly upon it; another, on which the yellow meadow vetchling apparently constitutes the leading feature; a third, irregular, patchy, and much afflicted with the sorrel-dock; and yet another, on which, at the time of our visit (August), the white-flowered umbels of the earth-nut put everything else in the shade,—these and the like appearances convince with an eloquence which the pen is powerless to imitate.

The land in Rothamsted Park has probably been laid down with grass for some centuries. No fresh seed has been artificially sown within the last fifty years certainly, nor is there record of any having been sown since the grass was first laid down. The experiments commenced in 1856, at which time the herbage appeared to be of uniform character. With few exceptions the same description of manure has been applied year after year to the same plot; and two plots, the third and twelfth, have been continuously unmanured. For the first nineteen years the first crop only was cut and carried away, and the second crop was usually fed off by sheep who were receiving at the time no other food. Of recent years it has been more and more the practice to make the second crop also into hay, and it is intended to adhere to this plan in future, weather permitting.

The produce of every plot is weighed as hay, and the result calculated per acre. Taking the average of the first twenty years, the unmanured plots, 3 and 12, gave the lowest yields of all, 21¼ and 24 cwt. respectively. Next above these is plot 5, manured with ammonia salts[1] at the rate of 400 lbs. per acre per annum, the yield giving an annual average of 26¼ cwt. per acre. The highest average recorded, 62½ cwt. per acre, resulted from a mixed manure, containing 500 lbs. sulphate of potash, 100 lbs. sulphate of soda, 100 lbs. sulphate of magnesia, 3½ cwt. superphosphate of lime, 600 lbs. ammonia salts, and 400 lbs. silicate of soda,—a tremendous dressing, by the way. The average yields on the other plots, each one of which received different manurial treatment from that of the others, range themselves between these extremes.

But the mere quantitative estimation of the results was a comparatively simple task to that of making a qualitative examination of each crop. The proximate analysis was into the three classes of gramineous herbage, leguminous herbage, and miscellaneous herbage, the last-named containing all plants not referable to the Gramineæ or the Leguminosæ; and even this task would not be a very difficult one. But when it is stated that in certain seasons a complete botanical analysis was made, whereby each species of plant was separated from all the others, then the irksomeness of the work will be appreciated. For the details of these analyses we must refer to the memoir itself, but the following is worth reproducing. "To quote an extreme case in illustration of the difference in the character of the herbage, and of the difference in the degree of difficulty of separation accordingly, it may be mentioned that whilst a sample of 20 lbs. from one plot in 1872 only occupied from four to five days in botanical analysis, a sample of equal weight from another plot in the same year occupied thirty days."

The total number of different species of plants that have been detected on the plots is 89; of these, 20 are grasses, 10 are leguminous, and the remaining 59 belong to miscellaneous orders. The 89 species comprise 59 dicotyledons, 26 monocotyledons, and 4 cryptogams, 3 of which are mosses (Hypnum); they are arranged under 63 genera and 22 orders. Of the miscellaneous plants there are 13 species of Compositæ, 6 of Rosaceæ, 5 each of Ranunculaceæ and Umbelliferæ, 3 each of Labiatæ, Polygonaceæ, Liliaceæ, Caryophylleæ, Scrophulariaceæ, and Musci, 2 each of Rubiaceæ and Plantagineæ, and 1 each of Cruciferæ, Hypericineæ, Dipsaceæ, Primulaceæ, Orchidaceæ, Juncaceæ, Cyperaceæ, and Filices. Six genera only were represented by more than one species; these were Ranunculus, 5 species, Rumex 3, and Potentilla, Galium, Leontodon, and Veronica, 2 each. The 20 species of grass comprise 14 genera; Festuca is represented by 4 species, Avena by 3, Poa by 2, and Anthoxanthum, *Alopecurus*, Phleum, *Agrostis*, Aira, *Holcus*, Briza, Dactylis, Cynosurus, *Bromus*, and Lolium by 1 each. The fact that the four genera whose names we have italicised were only represented by one species each serves to indicate somewhat the nature of the land. Had it been wet or marshy in parts, *Alopecurus geniculatus* might have been looked for as well as *A. pratensis*. Had not the plots been quite away from hedgerows, several species of Bromus might have accompanied *B. mollis*, while *Arrhenatherum avenaceum* and *Brachypodium sylvaticum* might also have been looked for. The total absence of Glyceria further shows the fairly dry character of the soil. Lastly, the 10 species of Leguminosæ fall under 5 genera—of Trifolium 4 species, Lotus and Vicia 2 each, Lathyrus and Ononis 1 each.

---

[1] "Agricultural, Botanical, and Chemical Results of Experiments on the Mixed Herbage of Permanent Meadow, conducted for more than twenty years in succession on the same land." Part ii., the Botanical Results. By Sir J. B. Lawes, Bart., F.R.S., Dr. J. H. Gilbert, F.R.S., and Dr. M. T. Masters, F.R.S. *Phil. Trans.*, Part iv., 1882. Pp. about 250.

[1] "Ammonia salts"—in all cases equal parts sulphate and muriate of ammonia of commerce.

Ten species of grasses occur on all the plots: *Anthoxanthum odoratum*, *Alopecurus pratensis*, *Agrostis vulgaris*, *Holcus lanatus*, *Avena flavescens*, *Poa pratensis*, *Poa trivialis*, *Dactylis glomerata*, *Festuca ovina*, and *Lolium perenne*. *Festuca eliator* was only found in one plot, and *F. loliacea* in two. *Phleum pratense* occurred in about one-fourth the number of plots, *Aira cæspitosa* in about one-half, *Briza media*, *Cynosurus cristatus*, *Festuca pratensis*, and *Bromus mollis* in sixteen or seventeen. No leguminous plant occurred in all the plots, but *Lathyrus pratensis* was found in nineteen plots, *Trifolium repens* and *T. pratense* in seventeen, *Lotus corniculatus* in sixteen, and *T. minus*, *T. procumbens*, *L. major*, *Ononis arvensis*, *Vicia sepium*, and *V. Cracca* only in one each.

These details will serve to indicate the nature of the flora of the plots. Certain miscellaneous plants common on many old pastures in this country are conspicuous by their absence. The dry and level character of the meadow will account for the absence of Caltha and Juncus. No species of Geranium is recorded. But the most noteworthy fact appears to be the absence of certain scrophulariaceous genera, which are by no means uncommon on old grass lands, namely, Bartsia, Euphrasia, and Rhinanthus. The quality of the land is probably too good for the first two, and the application of manure would certainly be against Euphrasia, but *Rhinanthus Crista-galli* is very common on old meadows, as, for example, in Derbyshire and Worcestershire.

The object which the authors kept in view in writing this section of their report was, in their own words, "to show both the normal botanical composition of the herbage, and the changes induced by the application of the different manuring agents, and by variation in the climatal conditions of the different seasons; and, as far as may be, to ascertain what are the special characters of growth above ground or under ground, normal or induced, by virtue of which the various species have dominated, or have been dominated over, in the struggle which has ensued." At the outset it was noticed that those manures which are most effective with cereals grown on arable land were also most active in increasing the quantity of grass amongst the herbage, and that the manures which are most beneficial to beans or clover produced the greatest proportion of leguminous herbage. Thus, the highest gramineous produce resulted from a highly nitrogenous manure, such as ammonia salts or nitrate of soda, with alkaline salts, particularly potash; but side by side with the increase in the total gramineous herbage there was a decrease in the actual number of species of grass. On the other hand, the highest percentage of leguminous produce was the result of a mixed mineral manure with potash. The percentage results on the following plots illustrate these points:—

	Plot 7.	Plots 3 and 12.	Plot 11.
Gramineæ	61·78	67·43	94·96
Leguminosæ	22·71	8·20	0·01
Other Orders	15·51	24·37	5·03
	100·00	100·00	100·00

Plot 7 was the most favourably manured for leguminous produce, it received mixed mineral manure alone, including potash; plots 3 and 12 were the two unmanured ones; plot 11 was the most favourably manured for gramineous produce, it received 800 lbs. ammonia salts with mixed mineral manure, including potash.

Special observations and complete botanical separations made at intervals of five years to determine the influence of seasonal variations show that "a given quantity of the produce grown under the same conditions as to manuring might be composed very differently in two different seasons."

The influence due to the special medium through which a particular plant-food, such as nitrogen, is presented to the plant, is aptly illustrated in the following extract:—"Because a particular grass, or other plant, is little benefited by ammonia salts for instance, it does not follow that it will not be favoured by nitrates; nor, because if while growing in association with other species it may not be specially benefited by a particular manure, does it follow that it would not derive advantage from the same substance when growing separately."

Nearly all the plants on the plots are perennials, very few are annuals, *Bromis mollis* being the only case amongst the grasses. The advantage possessed by deep-rooting over surface-rooting plants was well brought out in the droughty season of 1870, when the latter suffered considerably from lack of moisture. The locomotive power of underground stems is of great use to some plants: "the stock continues to grow at one end, year after year, the opposite end gradually dying away. In the course of a few years the plant therefore occupies quite a different position from that which it at first had." Notwithstanding the general rule that the chief effect of nitrogenous manures is to favour the extension of foliage and give it depth of colour, while that of mineral manures is to encourage stem formation and the production of seed, and notwithstanding that excessive nitrogenous manuring prolongs the development of the vegetative organs till perhaps the resources of the plant are exhausted or the season is over, while excess of mineral manures may induce premature ripening, yet so far as the experiments have gone no absolute change in the distinctive form of any plant has been effected by the prolonged use of the different manures, though changes of degree are sometimes very marked, as in the tufts of *Dactylis glomerata*.

The battle for life between the various species of plants growing in the meadow is dependent much less on the chemical composition of the soil than on its physical character, its capacity for holding water and its permeability to roots. The immediate source of victory lies very generally in the powerful root-growth of the survivors, the term "root" here covering all kinds of underground stem. The various influences affecting the struggle for existence amongst meadow plants are discussed by the authors in a fascinating manner, and this part of the memoir is of special value to the botanical student.

Every plant occurring on the plots is dealt with individually, and in the case of each grass and leguminous plant and of the more commonly occurring weeds, a table showing the relative predominance is given. The fact that plants closely allied morphologically may yet differ widely in their physiological endowments is strikingly illustrated by the two species of Poa, *P. trivialis* and *P. pratensis*. These two plants, sprung at no very distant period from a common ancestor—for this, we presume, is the morphological significance of their being placed in the same genus—differ only in the most trivial points: *P. pratensis* is smooth, stoloniferous, and has a blunt ligule; *P. trivialis* is rough, has no stolons, and possesses a long pointed ligule. We read that "the stolon-bearing *Poa pratensis* is specially benefited by nitrogenous manure in the form of ammonia salts (in combination with mineral manure), but not at all by nitrate of soda, whereas the more finely-rooted and non-stoloniferous *Poa trivialis* has declined markedly on the ammonia plots, but has remained very prominent on the nitrate plots, especially where the larger amount of nitrate was used with the mixed mineral manure." Thus in 1872, on plot 9 (mineral manure and ammonia salts) *P. pratensis* gave 22·67 per cent. of the total produce, and *P. trivialis* only 0·64; on plot 14 (mineral manure and nitrate of soda) *P. trivialis* gave 24·76, and *P. pratensis* only 2·57 per cent. It is suggested that the relatively shallow-rooting *P. trivialis* predominates on the nitrate plots by reason of its fine surface-roots arresting and taking up the nitrate before it has had time to penetrate too deeply; this plant invariably makes rapid growth upon the application of the nitrate of soda in the spring.

The remaining portion of the memoir is devoted to a discussion of the botany of each separate plot in each season of complete botanical separation, and is carried out with the same elaborate detail as the earlier portion. No one can read this memoir without being impressed with the great power, too frequently overlooked, possessed by the subterranean members of the plant body in deciding the struggle for existence; much of the internecine warfare is carried on in the dark.

It is quite possible, and indeed probable, that, had a similar series of experiments been simultaneously carried out in another part of England with a slightly different climate, and on a different kind of soil, the results might have differed, but only in slight details. Such a splendid series of experiments on grass land has never before been consummated, and the memoir embodying the results will well repay the most careful study and perusal not only of the agriculturist, but of the botanist, the chemist, and the evolutionist. It may perhaps be long before the great lessons learnt in Rothamsted Park have filtered down to those to whom they should be of most practical value, but we do not despair of a time coming when the intelligent manuring of grass lands for very specific objects will form a part of ordinary agricultural practice. Those who will put their hands to the plough in the field of agricultural research must be content to trudge along, laboriously and unnoticed, in the furrow. Their discoveries cannot be made in a week, or a month, as are many in electricity or in chemistry, but, like those at Rothamsted, which are now in their twenty-eighth year, and are still going on, they can only be looked for, even after the expenditure of much thought and of unflagging industry and perseverance, as "the long result of time."

W. Fream

PALÆOLITHIC MAN—HIS BEAD ORNAMENTS

EVERY one who has noticed the objects found in caves of Palæolithic date knows the evidence which supports the idea that cave men wore bracelets and necklaces, but the evidence that the older river-drift men wore similar ornaments is more obscure. Still, when one notices the extreme beauty and precision of make of some Palæolithic implements, one cannot help surmising that the more ancient savages of our old river sides also had sufficient personal pride and ideas of ornament to sometimes decorate their bodies with beads in a similar fashion with the cave dwellers.

Dr. Rigollot ("Mémoire sur des Instruments en Silex," p. 16) refers to the well-known foraminiferous fossil from the chalk—*Coscinopora globularis*, D'Orb. (sometimes found in river gravels with Palæolithic implements), as beads probably used by Palæolithic men; and Sir Charles Lyell ("Antiquity of Man," p. 119) says: "Dr. Rigollot's argument in favour of their having been used as necklaces and bracelets, appears to me a sound one. He says (Dr. Rigollot) he often found small groups of them in one place—just as if, when swept into the river's bed by a flood, the bond which united them together remained unbroken." Mr. James Wyatt of Bedford, in describing these bead-like fossils (*Geologist*, 1862, p. 234), says he had examined more than two hundred specimens, and on making sections of some of them he saw markings which appeared to indicate "drilling with a tool after the object was fossilised." In specimens from the chalk the hole through the fossil, though commonly straight, exhibits of course no artificial drilling but shows the structure of the foraminifer.

I am not aware of any confirmation hitherto made of the two curious observations noted above, but so little is at present known of the habits of river-drift men that the following notes may prove of some interest. Where there is so much darkness the slightest glimmer of new light is welcome.

After long searching for the Coscinopora at Bedford without result, I lighted on many examples at Kempston in 1880. In this year I found in a few days over two hundred examples; they occurred with unabraded implements and flakes and carbonised vegetable remains. After this date the Coscinopora again ceased, and from then till now I have met with but few examples. The finding of the above-mentioned large number of specimens all congregated together appeared to lend some confirmation to Dr. Rigollot's view, for it seems unreasonable to believe that so large a number could by any natural possibility find a position in one place in any river gravel.

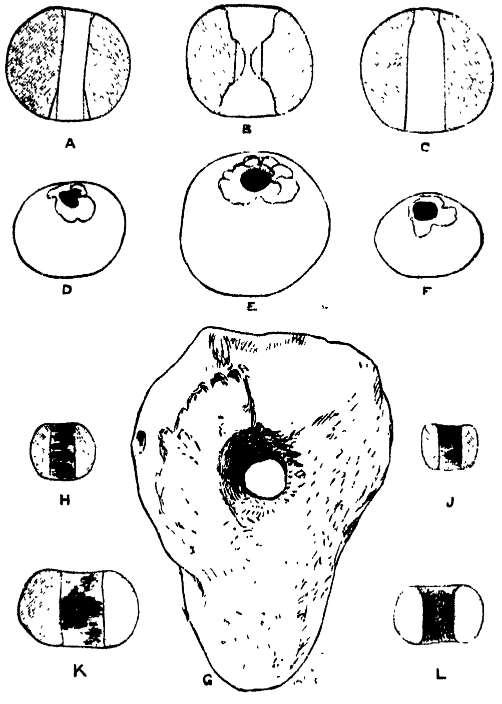
As my examples were found at Bedford, at a place where Mr. Wyatt must at one time also have found a considerable number, I naturally examined the specimens carefully to see if I could trace any artificial drilling or enlargement of the natural hole. I speedily noticed that the surface round each orifice in many of the beads was abraded as if by the constant contact of the bead next on a string. A few of the beads also had the hole artificially enlarged, sometimes at both ends, as at section A, sometimes in the middle, as at the section B, and sometimes at one end only, as at the section C. The dotted lines in these illustrations show the original natural orifice, the solid lines near the dotted ones show the enlargement by artificial drilling. The illustrations are all actual size. In most of the instances the drilling appears comparatively fresh, in others less so, but it must be remembered that the implements found with them were mostly unabraded, and vegetable remains were found. These specimens were found by myself. They were not touched or manipulated by the workmen. Other examples of these beads had one end near the orifice broken away as if in an attempt to enlarge the opening by breaking the substance of the fossil away as at D, E, F.

Whilst looking through the fallen material in the pit, the piece of naturally perforated fossil shell, illustrated actual size at G, attracted my attention. The hole is probably due to a shell-boring mollusk, but when I saw the object in the drift I distinctly noticed that a black substance entered at one side of the hole and emerged at the other; at the moment of picking the object up, this material fell to dust with part of the very friable surface of the fossil shell.

Some of the beads (as seen in section at H, J, K, L) also bore very distinct traces of a similar black substance within the orifice, although not seen till the sand and part of the black substance itself had fallen out. This black material I took to be the remains of part of the ligament on which the beads were originally strung by their Palæolithic owner, and with this idea in mind I sent some to an analytical chemist, who examined the material for me with the following result:—

"The testing for nitrogenous organic matters, of which animal tissues are composed, was tested in the same manner as testing water for such matter, that is, by converting it into ammonia; precautions were of course taken to eliminate from the results any ammonia already existing. The amount of ammonia was strikingly evident and showed with each bead examined separately. The blackening of the organic matter in the holes of the beads may have taken place in a manner similar to that of the formation of coal."

On testing the beads, which consist chiefly of carbonate of lime or chalk, without the black material in the orifice, the chemist reported that, "when treated in the same manner as those originally sent, they show the presence of a considerable amount of heterogeneous or animal organic matter, as was to be expected from their origin—but not, I think, so much as those with the black deposit."



Palæolithic Bead Ornaments (*Coscinopora globularis*, D'Orb.), showing traces of the original ligament and artificial enlargement.

Mr. A. Clarke, analytical chemist of Huddersfield, who also made an analysis for me, reported as follows :—

"I divided the bead into three portions. No. 1. The thin dark crust forming the internal portion of the ring; this is most certainly organic matter. No. 2. A powdery part between No. 1 and the main body of the ring, consisting of small quantities of carbonates of iron and lime. No. 3. The outer main body of the ring, mostly carbonate of lime, and a small quantity of silica; here there is only a trace of organic matter, but it is most distinctly present."

WORTHINGTON G. SMITH

IS IKTIS IN CORNWALL, AND DID IRON AND COPPER PRECEDE TIN?

At Penzance on October 19, 1883, I asserted that the invention of tin-smelting was Cornish, but disputed the claim of St. Michael's Mount to be the sole claimant to the title of Iktis, the tin-shipping port described by Diodorus Siculus 1800 years ago, and I thought the inventions of metals were in this order: (1) iron, (2) copper, (3) tin. We may consider the Romans invaded Britain purposely to obtain its metals, which were then worked extensively by the British inhabitants. I believe the Romans either adopted Celtic names of places or things, or translated their meaning. I find the Cornish district, or Land's End, described by Ptolemy the geographer in the second century as "Belerium," that is the land of mines, "bal" being Cornish for a mine. The word is also met with in Irish. In the same manner the skin boats used by the Cornishmen, which so much astonished the Greek travellers, were described by the Greeks under the name of "coracles," evidently a Celtic word from the Celtic root "cren" or "croen," skin. So tin, I think, is derived from the Irish word "teine," Welsh "tan," teine probably also expressing brightness. Even in the Malay Peninsula, in the East Indies, a word of similar sound, "timah," still stands for "tin," and not the Greek term for that metal "kassiteros."

Then the Cornish term "iarnn," for iron is similar to English "iron," German "Eisen," Welsh "haiarn," Greek "seiderion," in which *ei* is the important syllable. The Latin word "ferrum" is probably a form of "ierrum," and the Sanskrit "ayas" is for iron, metal. Nearly the same word for iron is therefore used in all the Aryan languages, while "æs" or "kalkos" stands for bronze or copper, and has only a comparatively local extension. The wide spread of the name for iron, or *ei*, is important, as it points to iron being the metal made before the division of the Aryan race, and therefore before copper or tin.

There is another and I believe new argument. The most easy process of copper-smelting, which even now is largely used, may have been the only plan known in prehistoric times. To use this process it was necessary to provide iron to precipitate copper from solution. At the present time 6000 tons of iron are sent annually to the Rio Tinto mines in Spain from Great Britain in order to precipitate the copper from solution.

It is possible that the discovery of the art of producing crude iron, which would be useful for precipitating copper, may have preceded the invention of bronze, and yet the art of forging difficult pieces may have been a later invention than that of casting bronze celts in metal moulds.

Iron, if not steel, appears to have been made in Egypt both in hearths and in crucibles certainly before 3124 B.C., but bronze was more used in Greece up to 650 B.C. than iron.

The smith in the sagas and folklore is the important person, not the caster or founder of bronze weapons. Why was the smith so important? Because he melted the small particles of gold found in the streams into small lumps, and with his hammer drew them out into wire and thin plates. Gold was made in such small quantities that it did not require large crucibles such as would be necessary for bronze. As iron was made by a simple welding or forging process, its production appears to be a more ancient art than bronze casting, which required large crucibles and mixing in exact proportions with tin, a process more difficult than in the infancy of metallurgy was likely to be invented. Then one ore of iron, ochre was the first metallic ore collected, long before the discovery of any of the metal. Ochre is found collected for use as a paint to ornament the cave men in the Palæolithic period, and is associated with limestone and charcoal. Accident in the fire might have thus led to the discovery of metallic iron in very early times. Such particles of iron placed in a certain stream in the Island of Anglesea (an early peopled district) would precipitate the copper in solution in that stream in a state of pure copper ready to mix with tin to make bronze.

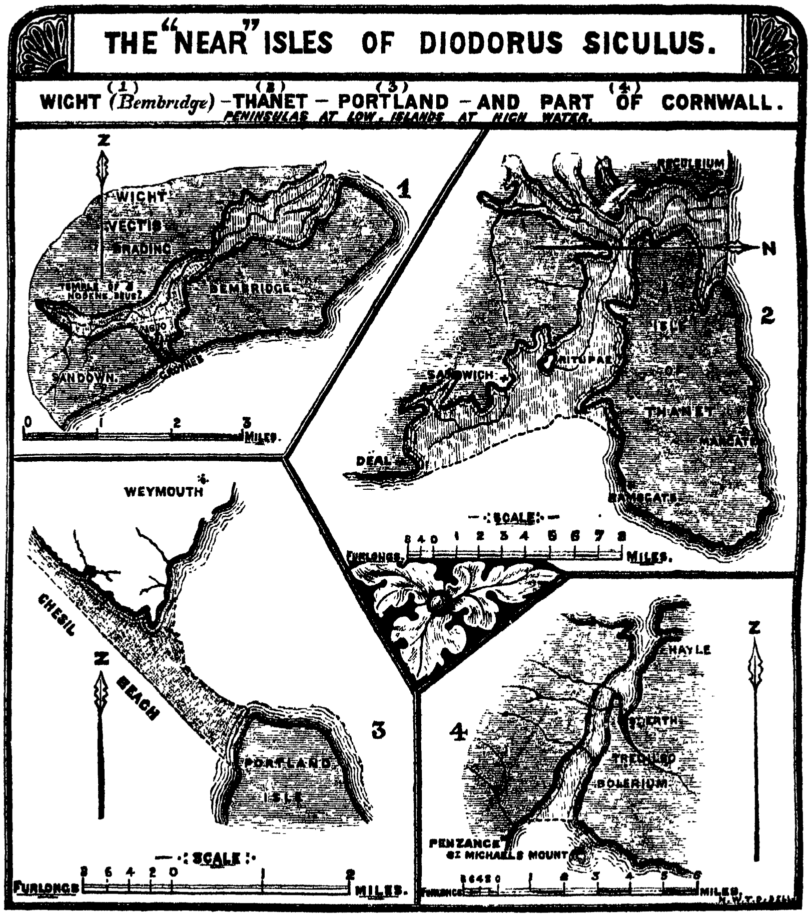
Another point of great interest in this question is the position of Roman roads, proving a prior metallurgical trade, and therefore some considerable civilisation. The Romans erected their Roman villas and camps always near Roman roads, and these roads appear always arranged for military or metallurgical purposes, never for protecting agriculture, or levying imposts on the Britons. There is historical evidence that the Romans did not introduce metallurgy into Britain.

We may observe there is a great concentration of Roman roads at Winchester (Venta Belgarum). Roads meet at the point of junction from Exeter with this town, for bringing Cornish or Dartmoor tin, or lead and iron from the Mendips, to the Hampshire coast; iron from

South Wales, and lead from North Wales. There were, near Winchester, several great ports for Continental trade, viz. Magnus Portus (Portsmouth), Trisantonis and Clausentum (Southampton). Winchester is near Beaulieu. Below Beaulieu, six miles, is Stansoar (stone) Point, from "stannum," tin. This is nearly opposite Gurnard's Bay (Gubernators, across the Solent two miles), where there are remains of Roman villas. Thence to Newport and Brading, where the great Roman discoveries have been recently made. Among the "Islands of Britain" Ptolemy gives one as "Vectis," in Celtic Wyth.

Now Vectis has been hitherto treated as if it were only the name of an island, the Isle of Wight; but vectis is really the Latin term for a bolt, or security, and was probably applied to harbours, and is a translation of "Gwyth." A lock means also a canal lock.

If Prof. Rhys is right,[1] that "Ictis" and "Itius" are the same word, we may go further and say that the Portus Itius, from which Cæsar started from Britain, containing his 800 ships, was merely a technical term for a vectis or secure harbour attached to a town, such as that at the mouth of the Liane (Boulogne). It is only a century and a half since the natural basin of Boulogne has been partly filled up by the sea sand, and there was an estuary supplied by the Liane stream at the time of Cæsar, not unlike those drawn by me in shape, but without a through passage.



In fact, not only along the English coast, where Dungeness Beach has blocked up the Roman Port Lymne, and the points where four islands have been joined to the mainland, as shown in the drawings, Figs. 1, 2, 3, and 4, but on the French coast great changes have been made by the same causes. At Sangatte and Calais, Wissant, Ambleteuse, Boulogne, St. Michael's Mount, and in fact at many places along the coast of the Pays Bas, the same filling up can be observed.

Cæsar's port of embarkation, Portus Itius, may have been named in the same sense as, according to Prof. Rhys, the old Irish wrote of the English Channel, viz. as Muir an Icht, which he renders the Sea of Icht, and which, according to the view I suggested, would be the sea of the passage, evidently a different meaning, although from the same roots, to the name, which, with the addition of Portus, we find in Cæsar. The term Portus Itius evidently was applied by the Roman writers to the harbour of Boulogne, although the city itself was called Gessoriacum. I think this philological explanation and the fact of the distance from Portus Itius (given by Strabo) thirty miles to Britain, removes every difficulty in the way of settling the position of the port from which Cæsar started. Of course the term Portus Itius might also apply to St. Valery-sur-Somme, where a passage has been partly closed, as at Marazion, in the historical period, but the distance given by Strabo is against it. Species of mollusks are found at both places, Marazion and St. Valery, not now living on the coast, and probably these estuaries or passages were only entirely open in the Crag period.

---

[1] In a letter to A. Tylor, November 6, 1883.

I have said Vectis is equivalent with the Celtic word "gwyth," a passage. Now there is a closed passage or haven (a gwyth, or vectis, or iktis) from Sandown to Bembridge in the Isle of Wight (Fig. 1). From this passage the whole island gets its name "Gwyth" in Celtic, Latin "Vectis," Saxon "Wiht," English "Wight," never spelt "White," although it has white chalk cliffs.

The safety of any of the harbours called Vectis or Iktis arose from the fact of these islands (or parts of them) near the coast of Britain being peninsulas at low water and islands at high water. These were, therefore, typical natural harbours. The Greek writers, Diodorus Siculus and others, insist particularly upon this property of change with the tide. The remarkable tide contrasted strongly with the different circumstances in the Mediterranean. Now the prevailing winds on the south coast of England have caused modern beaches to form, particularly at all of these four passages on the south coast of England, and many of the passages have been closed, as we know, in the historical epoch. Their ancient form is clearly shown in my woodcut. Now the sea is entirely shut out by modern beaches and works.

The drawings show the changes which have occurred in Fig. 1, the Isle of Wight. Fig. 2 is the passage between the Isle of Thanet and Kent, closed in the historical period between Ritupæ and Regulbium. In Fig. 3, the Chesil Bank, has filled up the old waterway between the Isle of Portland and the mainland. Fig. 4, passage from St. Michael's Mount to Hayle. Gravel and stream tin-drift, closing up the ancient passage from near St. Michael's Mount at Marazion to Hayle.

The type of all that has happened is well seen, Fig. 1, Vectis, the Isle of Wight. Even in 1670 there was only a groyne and a small alluvial deposit near Sandown. Nearly all the passage to Bembridge was an estuary; now it is nearly all dry land.

The term "vectis" in Latin, or "iktis" in Greek, was no doubt applied to all the passages in these four islands.

The Cornish tin no doubt came in coracles, and by land on horses, to Magnus Portus or to Stansoar Point for shipment to Brading, and was shipped from these Hampshire ports and Isle of Wight ports to the banks of the Seine, to be carried on horseback in thirty days to Marseilles. Thus both the Bembridge peninsula and St. Michael's Mount were shipping places for tin, and both were properly called Iktis and Vectis, and as usual we find there was no error in the Greek observations.

Then as to the period when the contour lines of the south coast began to change. The Crag period was that in which the great estuaries round the British coast began to be filled up. Then pebbles and sand were driven along the coast. I believe all the four channels in the drawing, were open in the Crag period, and gradually closed up in the long period which intervened between the Crag and the present time. The continuous filling up has also occurred in the estuaries and passages on the opposite coast of the English Channel. It is probable that Portus Itius, at Gessoriacum? (Boulogne) obtained its name in a similar manner to Vectis and Iktis as I have already stated.

We find pure iron B.C. 3124 in Egypt. If iron was a necessity for the production of copper, and the metal tin was of no use without copper, we may place the inventions of the metals in the following order: (1) iron, (2) copper, (3) tin. A. TYLOR

THE BEN NEVIS OBSERVATORY

SINCE the formal opening of the Observatory on October 17, workmen have been engaged in fitting up and finishing the interior, and pushing forward the provisioning of the establishment with tinned meats, biscuits, tea, coffee, &c., capable of lasting for six months, with fuel for a like period. Nothing that could be thought of has been left undone to render the observers as comfortable as possible during the winter. The telegraph cable is now in working order from the Observatory to Fort William, so that communication is always possible with the outer world. Mr. Omond, the superintendent, and his two assistants took up their residence on the top of the Ben about a fortnight ago; and it is extremely gratifying to learn that the building, every part of which during erection, and for some time after being roofed over, was soaked with water, is now thoroughly dry; the walls, roof, and windows have been officially inspected, and found to be perfectly tight in every respect; and in corroboration of this, during the storm of Thursday, the 8th inst., none of the finer snow particles of that elevated region entered the dwelling. As an additional protection against the severe weather which may happen, a large roll of tarpaulin, thirty-five feet long, was carried on the shoulders of twelve men to the top on Monday last week, and securely fixed over the roof of the building.

In a letter dated the 14th inst., Mr. Omond states that the Sunday previous was one of the finest days he ever saw; that Monday and Tuesday were nearly as good; and that on the Wednesday only the distant view was shut out by haze. Up to that date the top of the Ben had been all but free from stormy weather; indeed, while tempestuous weather raged below, the wind rose to a gale only on Thursday the 8th. A telegram was received direct from the Observatory on Thursday last week, which stated that the temperature for the day had been minimum 17° and maximum 28°, while inside the Observatory the temperature was 55°, which happened to be exactly the temperature of the Scottish Meteorological Society's office in George Street at the time.

A meeting of the directors was held at Edinburgh on the 15th inst., Sir William Thomson in the chair, at which Dr. Sanderson, the Treasurer, reported that the subscriptions now intimated amounted to a little over 5000*l*., nearly three-fourths of which sum had been subscribed since the middle of May last.

A scheme of work for the coming winter, consisting of hourly observations by night as well as by day, was agreed upon. The observations include the barometer; dry, wet, maximum, and minimum thermometers; direction and force of the wind; rain, sleet, snow, and hail; evaporation from snow; species, direction, and velocity of upper and lower cloud strata; and sunshine, together with thunder, lightning, halos, auroras, meteors, &c. In addition to the regular observations, Mr. Omond is to conduct physical inquiries into the hygrometry of this boreal climate by an instrument specially designed by Prof. Chrystal; inquiries as to the direction and speed of the wind and optical phenomena by instruments specially designed by Prof. Tait; and inquiries as to the best modes of conducting the observations under the special difficulties presented by the climate of Ben Nevis.

All the hourly observations will be extended on a daily sheet, three copies of which will be made, one for the Observatory, and two for the Scottish Meteorological Society, one of which will be sent to the Scottish Meteorological Council, London. Forms have also been supplied for monthly summaries of the observations. It has further been arranged that a series of similar observations at 8 and 9 a.m. and 2, 6, 9, and 10 p.m. be made at Fort William by Mr. Colin Livingstone, one of the Scottish Meteorological Society's observers.

A Redier's continuously-recording barograph and a Richard's continuously-recording thermograph have been supplied to the Observatory, and also to Mr. Livingstone, to be used as interpellation instruments. By the double set of hourly observations thus obtained, comparisons may be made between the atmospheric conditions on the top of the Ben and those at sea-level, which are of such vital importance in the larger questions of meteorology. It may be noted here that it was found necessary to take the barometer, which had been for upwards of two years exposed in the cairn to the severe weather of the Ben, to Edinburgh to be thoroughly overhauled. It has since been conveyed to its permanent place in the Observatory, and is in excellent order. The full equipment of the Observatory is delayed till next summer, when the directors will have before them Mr. Buchan's report on the instruments in use at the different European meteorological observatories he visited in the autumn, the work of the Observatory during the next eight months, and the results of Mr. Omond's investigations into different methods of observing on Ben Nevis.

NOTES

We deeply regret to announce the death of Sir William Siemens on Monday night, at the age of sixty years. His death is attributed to rupture of the heart, the result of a fall which he sustained a fortnight since. We must defer to next week a detailed notice of Sir William's career and work.

It is proposed to acquire for the Cambridge Museum of Comparative Anatomy the beautiful collection illustrating the fauna of the Bay of Naples, which Dr. Dohrn exhibited at the International Fisheries Exhibition. The cost will be only 80*l*., little over that of the glass jars and the alcohol in which the animals are preserved.

Lieut. Wissmann, the African traveller, has just left Hamburg again on another three years' exploration in the Congo region. He has undertaken to furnish the Royal Museum at Berlin with all the natural history specimens which he may collect during his travels, and has even been prevailed upon by some anthropologists to take plaster casts of all the races he may come in contact with.

The widow of the late Mr. John Elder, of Glasgow, has given the munificent sum of 12,500*l*. to the University of Glasgow for the purpose of endowing a chair of naval architecture.

We regret to learn of the death of Mr. James Stewart, C.E., who has done so much for the exploration of the region around Lake Nyassa. At the time of his death he was engaged in the formation of a road between Lakes Nyassa and Tanganyika.

Dr. Hector, F.R.S., stated at a recent meeting of the Wellington (N.Z.) Philosophical Society, that his two self-registering barometers had shown a remarkable up and down vibration on the revolving drum upon which the record is marked on dates corresponding with those of the Sunda earthquake, and a severe earthquake twenty-six hours afterwards, which was felt all along the northern coast of Australia. This agitation was quite distinct from those caused by ordinary atmospheric influences. He attributed the curious tidal disturbances which occurred on the New Zealand coast in August to those earthquakes.

In a letter from Maranhao, Brazil, the writer states that from August 31 up to September 6, the sun, until 7 a.m., could be looked at without the least difficulty, its light being as soft and pale as the moon's.

At its meeting, October 27, *Science* states, the Philosophical Society of Washington listened to a communication by Dr. T. N. Gill on the ichthyological results of the voyage of the *Albatross*, and to one by Prof. A. Graham Bell on fallacies concerning the deaf. Dr. Gill described two anomalous fishes, one of which required the institution of a new order.

Herr Jacobson, who has spent four years on the north-west coast of America in making ethnological collections for the Berlin Museum, has recently returned, and will sail for Europe. Dr. Leonhard Stejneger has arrived in San Francisco, *en route* for Washington. He has spent a year in Behring Island in the study of its fauna, and in collecting remains of the extinct Arctic sea-cow.

At the recent meeting of the American Association, Mr. C. V. Riley read a paper on "Some recent discoveries in reference to Phylloxera." Every new fact, he said, in the life-history of the insects of this genus has an exceptional interest, because of its bearing on the destructive grape-vine Phylloxera. The genus is most largely represented in this country by a number of gall-making species on our different hickories, and the full annual life-cycle of none of them has hitherto been traced. The galls are produced, for the most part, in early spring; the winged females issue therefrom in early summer; and thence forth, for the remainder of the year, the whereabouts of the insect has been a mystery. The author has for several years endeavoured to solve this mystery, and at last the stem-mother (the founder of the gall), the winged agamic females (issue of the stem-mother), the eggs (of two sizes) from these winged females, the sexed individuals from these eggs, and the single impregnated egg from the true female, have been traced in several species. There is some evidence, though not yet absolutely conclusive, that this impregnated egg hatches exceptionally the same season; also, of a summer root-inhabiting life. In *Phylloxera spinosa*, which forms a large roseate somewhat spinous gall on *Carya alba*, and which has been most closely studied, the impregnated egg is laid in all sorts of crevices upon the twigs and bark and in the old galls, in which last case they fall to the ground. Up to this time they have remained unhatched, and will in all probability not hatch till next spring, thus corresponding to the "winter egg" of the grape Phylloxera.

The *Times* Calcutta Correspondent, in speaking of the possibility of opening up Thibet to Indian trade by way of Darjeeling, states that the Prime Minister of the Lama at Shigatze, said to be a most intelligent man, sent recently to Darjeeling for a supply of English books, photographic and other scientific apparatus.

The piercing of the Arlberg Tunnel was unexpectedly completed on Tuesday afternoon last week. In length the new tunnel ranks third among the great tunnels of the world, its length being 10,270 metres, while the Mont Cenis Tunnel is 12,323, and the St. Gothard 14,900 metres. But while the excavation of the first lasted no less than fourteen years and a half, and that of the second about eight, the Arlberg Tunnel will have taken, when vaulted and ready to receive the first locomotive, not more than four years, thanks to the experience acquired during the construction of the first two Alpine tunnels, and to some innovations which constitute another important step in the art of engineering required for the construction of large tunnels. The engineers of the St. Gothard Tunnel introduced dynamite for blowing-up the rock, already pierced through by the boring machine, which useful tool was naturally not disregarded in the construction of the new tunnel. It was also only natural that the Ferroux percussion boring machine, first introduced at the Mont Cenis works, should be again employed, under the supervision of the inventor himself, who in the meantime had considerably improved his powerful boring instrument; but this time the Brandt turning borer, first employed at the works of the St. Gothard, was allowed to compete with the Ferroux percussion borer, the former being used in boring on the tunnel's western side, and the latter on the eastern. To this end, several streams from the heights of the snow-covered Arlberg were gathered on the eastern side into reservoirs, from which two turbines and three water columns were directed to the machines, which compressed the air to five atmospheres, with which the Ferroux borer was worked; while on the western side pumped water was pressed through pipes to the tension of over a hundred atmospheres, to work the Brandt turning borer, which cuts cylindrical blocks of rock from the mountain. The eastern entrance to the Arlberg Tunnel—namely, St. Anton—is 1300 metres above the level of the sea, while the western entrance is only 1215 metres, by which difference a good ventilation of the future railway tunnel seems secured. The vaulting and all other necessary works will be finished at the latest on August 1, 1884.

A MEETING has been held at Chester, presided over by the Duke of Westminster, to take steps to provide the city with a museum, which is intended to be a centre of scientific information for Cheshire and North Wales. North Wales was represented at the meeting by the Duchess of Westminster, Earl Grosvenor, and Sir Robert Cunliffe, Bart.; the Chester Natural Science Society by its president, Prof. T. McKenny Hughes; and the Chester Archæological Society by Dean Howson and Mr. H. Tollemache, M.P. It was decided that the building should accommodate both these societies and the School of Art. The Duke of Westminster announced his intention of giving the greater part of the proposed site, and 4000*l.* towards the building fund.

THE Council of the New University College of South Wales, at Cardiff, have resolved to try to raise 3000*l.* for mechanical laboratories.

THE inaugural meeting of the International Electrical Association took place in Paris on the 15th in the large hall of the Société d'Encouragement. M. Cochery was voted by acclamation Honorary President, and M. Berger Acting President. The number of adhesions exceeds 1000.

THE following is an illustration of what private enterprise may effect for the benefit of science. When the Swedish ship *Monark* was leaving Sweden last year for Australia the second officer on board applied to the Zoological Museum at Upsala for the loan of a trawl and some vessels for preserving natural history objects. The results have been a collection of some 120 species of fish, 50 of insects, some birds, and about 100 varieties of the lower sea fauna of the Pacific, which have now arrived at Upsala.

ON November 2 the Imperial Russian Academy of Science celebrated its hundredth year with great ceremony. Count Tolstoy, the President and Minister of the Interior, acted as chairman.

MR. GAMÉL of Copenhagen has placed the *Dijmphna* at the disposal of Lieut. Hovgaard for an Arctic expedition next year.

AT the Royal Institution Prof. Dewar will give six lectures at Christmas (adapted to a juvenile auditory) on "Alchemy in Relation to Modern Science." Before Easter, 1884, courses of lectures will be given by Mr. R. Stuart Poole, Professors McKendrick, Pauer, Tyndall, and Henry Morley, Capt. Abney, and others. The programme of the Friday evening arrangements will be issued shortly.

A SLIGHT shock of earthquake was felt on Friday at Malaga. A shock was also felt at Chios on the 16th. An earthquake occurred on the 19th at Vallo della Lucernia in the province of Salerno, Italy.

THE additions to the Zoological Society's Gardens during the past week include an Ourang-outang (*Simia satyra* ♂) from Borneo, presented by Mr. William Cross; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Mrs. F. R. Flindell; a Hobby (*Falco subbuteo*), captured at sea, presented by Mr. C. Heat; six American Box Tortoises (*Terrapene carinata*), a Stink-pot Terrapin (*Aromochelys odorata*), seven Spotted Lizards (*Holbrookia maculata*), a Long-nosed Snake (*Heterodon nasicus*), two Striped Snakes (*Tropidonotus sirtalis*) from North America, presented by Mr. Samuel Garman, C.M.Z.S.; a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, a Cerastes Viper (*Vipera cerastes*) from Egypt, deposited; a Sykes's Monkey (*Cercopithecus albigularis*) from East Africa, a Negro Tamarin (*Midas ursulus*) from Guiana, an Indian Badger (*Arctonyx collaris*) from Assam, two Père David's Deer (*Cervus davidianus*) from Northern China, a Downy Owl (*Pulsatrix torquata*) from South America, purchased; a Sambur Deer (*Cervus aristotelis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

BRORSEN'S COMET.—Of the known comets of short period, two will arrive at perihelion in 1884, viz. D'Arrest's on January 13, and Brorsen's about September. The former has been sought after for several months, but hitherto, so far as we are aware, without success, and there now seems a probability that (as indeed was rather to have been anticipated) it will pass unobserved at this return. The second comet was discovered by Brorsen, an amateur at Kiel, on February 26, 1846, and ten days' observations sufficed to show that its period of revolution was about five and a half years: it afforded one of the most striking instances of a close approximation to the period being deduced from a short course of observation, Mr. Hind having inferred a revolution of 5·519 years from observations between February 28 and March 10 (*Astron. Nach.*, No. 557), while the exact period at the time is now known to have been 5·568 years. The comet has been since observed at its returns in 1857, 1868, 1873, and 1879, though missed in 1851 (perhaps through some confusion as to the date of perihelion passage), and again in 1863. The ephemeris for the last appearance in 1879 was prepared by Prof. L. R. Schulze of Dobeln, after the calculation of planetary perturbations since the return in 1873, the perihelion passage being fixed to March 30·0771 Greenwich M.T. The computed positions differed considerably from those observed, as was shown in M. Otto Struve's comparison with his own observations (*Bulletin de l'Académie des Sciences de St. Petersbourg*, t. v.), and these differences led him to remark:—"Eine Änderung in der angenommenen Perihelzeit würde für sich allein wahrscheinlich nicht genügen." It will be found, however, at the end of April or beginning of May. The errors may be removed by the assumption of a later time of perihelion passage; or by taking it March 30·5418 Greenwich M.T., a difference of + 0·4674d. from the computed epoch. Thus for the observation on April 30, we find, taking the differences in the order (c – o):—

	$\Delta\alpha$		$\Delta\delta$
By ephemeris	+ 1m. 38s.	...	+43′·8
With corrected perihelion	– 0m. 6s.	...	+ 0′·2

The mean sidereal motion determined by Dr. Schulze for 1879 would, without perturbation, bring the comet to perihelion again about 1884, Sept. 14·5, at which time it would be situate in about right ascension 154° with 14° north declination, distant from the earth 1·41, consequently rising more than two hours before the sun. The conditions are therefore likely to approach those under which the comet was observed in 1873.

Some six months after the discovery of this comet in 1846 attention was directed by Mr. Hind (*Astron. Nach.*, No. 582, and in a note to the Royal Astronomical Society) to the near approach which it must have made to the planet Jupiter in May, 1842, a first calculation indicating that on May 20 the distance between the two bodies was less than 0·05 of the earth's mean distance from the sun. This point was more closely examined by D'Arrest from improved elements in 1857 (*Astron. Nach.*, No. 1087); he found that the closest proximity occurred May 20·6924 Berlin M.T., when the comet was distant from the planet only 0·05112, and, carrying his computation backwards to the time when the comet entered the sphere of activity of Jupiter, he assigned approximately its elements previous to that time. A more elaborate investigation of the circumstances attending this near approach has been lately made by Dr. Harzer, in an inaugural dissertation published at Leipzig in 1848; he finds for the time of perijove passage, 1842, May 27·2849 Berlin M.T., and for the distance 0·05471; the elements prior to the great perturbation in this year are determined, and have been already transcribed in NATURE; they present a resemblance to those of the first comet which appeared in 1798, about which year Brorsen's comet might have been in perihelion; Dr. Harzer nevertheless expresses the opinion that, although Messier's observations of the comet of 1798 might be open to some degree of uncertainty, it is doubtful whether they would admit of being represented by an elliptical orbit with a short period. He had found the revolution prior to 1842 to be 5·170 years.

THE NAUTICAL ALMANAC.—The volume of this ephemeris for 1887 has been published during the past week, the contents being generally the same as in previous years. The track of the total solar eclipse of August 19 is given in detail for the greater part of the course, and the maximum duration of totality is found to be 3m. 50s., the central eclipse with the sun on the meridian falling in longitude 102° 0′ E. and latitude 53° 47′ N. The Greenwich list includes four occultations of *Aldebaran* during the year and one of *Regulus*.

The average annual sale of the *Nautical Almanac* during the last five years has exceeded 15,500, though many maritime nations have now their nautical ephemeris.

THE PHILOSOPHICAL SOCIETY OF GLASGOW

THE *Proceedings* for 1882-83, pp. 592, 23 plates, and 3 maps, have just been issued, and contain the following papers:—On insensibility arising from a deficiency of oxygen in the air, by Dr. Wallace, president; on technical education, by David Sandeman and E. M. Dixon, B.Sc.; on the decay of building stones, by Dr. Wallace; on some new infusoria, by William Milne, M.A.; note on Lippmann's capillary electrometer, by Dr. McKendrick; on milk and milk pollution, by Dr. John Dougall; on Struther's process for pulverising diamondiferous ore, by Wallace Fairweather, C.E.; on the use of litmus, methyl orange, phenacetolin, and phenolphthalein as indicators, by R. S. Thomson; on approximative photometric measurements of sun, moon, cloudy sky, and electric and other artificial lights, by Sir William Thomson; on the preservation of food by cold, by J. J. Coleman; on the clauses in the Glasgow Police Bill having reference to the prevention and mitigation of disease, by Dr. Ebenezer Duncan; on the ships and shipping trade of Great Britain, by N. Dunlop; on the iron ore industry of the north of Spain, by J. J. Jenkins; on the use of rosolic acid as an indicator, with additional notes on phenolphthalein and methyl orange, by R. S. Thomson; on architecture in Glasgow, by J. Sellars, jun., I.A.; on the water highways of the interior of Africa, with notes on slave hunting and the means of its suppression, by James Stevenson, F.R.G.S.; on a new seismograph, by Thomas Gray, B.Sc.; on the fertilisation of flowers, by Rev. A. S. Wilson, M.A.; on algin, a substance obtained from some of the commoner species of marine algæ, by E. C. C. Stanford; on chemical industries, by R. R. Tatlock; on nitroglycerine, dynamite, and blasting gelatine, by George McRoberts, manager of the Works of Nobel's Explosives Company; on the action of heat and the chlorides of phosphorus upon the water salts of hypophosphorus, phosphorus, and phosphoric acids, by Dr. Otto Richter; on a volumetric process for the estimation of cobalt and nickel, by Dr. John Clark; and, on the development and generic relations of the corals of the carboniferous system of Scotland, by James Thomson, F.G.S.

The society has at present 19 honorary, 10 corresponding, and nearly 700 ordinary members, and is about to enter on its eighty-first session. In addition to the ordinary meetings of the society, held fortnightly, there are sections for architecture, biology, chemistry, sanitary science and social economics, and geography and ethnology.

RESEARCHES ON SPARK SPECTRA

The Disappearance of Short Lines

IT was shown in a former Report of this Committee (Southampton meeting) that the spectra of metallic solutions were the same as those from metallic electrodes line for line, even short and weak lines being reproduced. The principal difference observable in the two spectra was a lengthening of the short lines when spectra were taken from solutions, so that discontinuous lines became long or continuous lines. A few instances of short lines disappearing have also been noticed, but such disappearances occur only when the lines are so short, mere dots, in fact, that no solution can contain a quantity of the metal sufficient to yield an image of them. Certain very short lines in the spectrum of metallic zinc are an example of this. Very short lines in the spectrum of aluminium were not reproduced by solutions of the chlorides except when the solutions were very strong, and then they always appeared. It may thus be seen that the quantity of metal present in the compound determines the presence of these lines.

The Lengthening of Short Lines.—It was remarked that in certain cases metallic electrodes showed a different spectrum according to whether the spark was passed between dry or wet electrodes. Thus it was pointed out that when iridium electrodes are moistened with calcic chloride, discontinuous lines which are very numerous in this spectrum become continuous; and on further examination into this matter it has been found that even moistening with water has the same effect. Hence the supposition, of which there seemed some possibility but no proof, that a chloride of the metal was formed is found to be untenable. The very short lines in the spectrum of zinc were lengthened by the action of water upon the electrodes. It has now been proved beyond doubt that this peculiar variation in the spectra is caused by the cooling action of the water upon the negative electrode, which in effect is the same as a strengthening of the spark, since by heating the electrodes a reverse action is the result.

Alterations in the Spectrum of Carbon.—As already stated in the previous Reports, graphite electrodes have been generally employed for the production of spark spectra from solutions. A portion of the work in connection with this subject included an investigation of the effect of water and of saline solutions in varying the spectrum of carbon. It will of course be readily understood that as carbon is capable of combining with oxygen and nitrogen, that different spectra might be obtained by making one or other of these gases the atmosphere surrounding the electrodes, but it is not so easy to explain why graphite points should give two different spectra in air when dry, and a third spectrum, again different, when moist, the same spark conditions being maintained.

Three such spectra have been photographed, but without the aid of maps their peculiarities are not capable of exact description. The maps which were drawn were presented to the Royal Society, together with a communication on this subject, three months since, so that they are not at present available. It may be said, however, that the difference between the two spectra taken from dry electrodes in air consists of the omission of a certain number of the less refrangible lines, which lines have undoubtedly been identified with carbon.

Spectra of the Non-Metallic Constituents of Salts.—A long series of experiments has been made with the object of determining the non-metallic elements which are capable of yielding spark spectra when in combination with the metals. Fluorides, chlorides, bromides, iodides, sulphides, nitrates, sulphates, selenates, phosphates, carbonates, and cyanides yield nothing. On the other hand, hydrochloric acid solutions of arsenites and antimoniates yield the spectra of arsenic and antimony. Borates and silicates in solution yield very characteristic spectra of the non-metallic constituents, but if the solutions be prepared from sodium salts the lines of the metal do not appear in the case of borates, and only the strongest sodium line ($\lambda = 3301$) can be observed in the spectra of silicates, even when concentrated solutions are used.

Line Spectra

BORON Wave-lengths	SILICON Wave-lengths
3450·1	2881·0
2497·0	2631·4
2496·2	2541·0
	2528·1
	2523·5
	2518·5
	2515·5
	2513·7
	2506·3
	2435·5

These are the first spectra of boron and silicon obtained from metallic salts.

---

[1] Report of the Committee on the Comparison of the Spark Spectra of the Elements with Spectra of Solutions of their Compounds, drawn up by Prof. W. N. Hartley.

In Messrs. Liveing and Dewar's map of the carbon spectrum (*Proc. Roy. Soc.* vol. xxxiii. p. 403), and in the list of the carbon lines and in the map of the iron spectrum (*Phil. Trans.* part 1, 1883), a number of lines are given which are absent from the photographs of the spectrum of graphite published in the *Transactions of the Royal Dublin Society* and in the *Journal of the Chemical Society* (vol. xli. p. 90). Many hundreds of spectra taken between graphite poles have failed to show a trace of these lines, and as the spectra have been photographed under very various conditions, it is scarcely likely that the lines in question are really carbon lines. They have now been identified in the spectrum of silicon.

Liveing and Dewar's carbon lines				Silicon lines (Hartley)
Spark[1]		Arc[2]		
—	...	2881·1	..	2881·0
2541·0	...	—	...	2541·0
2528·2	...	2528·1	...	2528·1
2523·6	...	2523·9	...	2523·5
2518·7	...	2518·8	...	2518·5
2515·8	...	2515·8	...	2515·5
2514·0	...	2514·1	...	2513·7
2506·3	...	2506·6	...	2506·3
		2478·3	...	—
		2434·8	...	2435·5

From this it appears that, in the spectrum of the arc, carbon yields but one line in the ultra-violet, wave-length 2478·3. It is perhaps a little doubtful whether the line with wave-length 2434·8 is due to silicon or not.

The Spectrum of Beryllium.—The researches made for the purpose of this report have been useful in furnishing evidence leading to a determination of the probable position of beryllium among the elements. It has been proved that the spectra of metallic solutions are identical with those of the metals themselves, and it is therefore obvious that characteristic spectra may be obtained from concentrated solutions of nitrates or chlorides when metallic electrodes are not procurable.

It was resolved to photograph the spectrum of beryllium, as obtained from its chloride, in order to observe the character of its lines and the manner of their grouping. The following were the lines observed :—

SPECTRUM OF BERYLLIUM

Wave-length		Description
3320·1	... ...	Strong, sharp.
3129·9	... ...	Very strong, extended.
2649·4	... ...	Strong, sharp.
2493·2	... ...	,, ,,
2477·7	... ...	,, ,,

The first two numbers differ slightly from those given in the *Journal of the Chemical Society* (June, 1883), but they are believed to be the more accurate. The previous measurements of the lines of beryllium were two given by Thalén (Watts's "Index of Spectra"), with wave-lengths 4487 and 4575, and two lines very close together given in Cornu's "Map of the Solar Spectrum," wave-lengths 3130 and 3130·4. It will be observed that in the spark spectrum only one line corresponding to the first of these is observed, viz. 3129·9. There is probably a difference in this case between the arc and the spark spectra, because there is no difficulty in distinguishing between two lines differing by 0·4 of a tenth-metre, and under various conditions two lines have never been observed at this point in the spark spectrum. On the other hand, such differences are by no means unusual.

Regarding the views held by Emerson Reynolds, Nilson and Pettersson, and Brauner on the subject of beryllium, however wanting in harmony they may be in detail, they at least agree in assigning a value not greater than 13·8 and not less than 9·2 to its atomic weight. The former number implies that the metal is a triad, the latter that it is a dyad. In the former case it must belong either to the series of elements of which aluminium, gallium, and indium are members, or to a sub-group of rare earth-metals, to which yttrium and scandium belong. In attempting to accommodate the element with a position in either series we are met by a serious difficulty, namely, that not only is the atomic weight out of keeping with the periodic law (a point which cannot be discussed here), but its spectrum is altogether different from the spectra typical of either class.

There is a periodic variation in the spectra of the elements as well as in their atomic weights and chemical properties, and we cannot put the periodic law out of mind in considering the position of beryllium.

Now the spectra typical of the triad group, of which aluminium and indium are the first and third terms, consist of three pairs of lines harmonically related, the intervals between the individuals of each pair increasing with increased refrangibility of the rays in each spectrum, while the intervals between the individuals in each pair in different spectra increase with the increase of atomic weight. The interval between each pair of lines contains an isolated ray. As the atomic weight of beryllium is less than that of aluminium, it should have a spectrum in which the same grouping appears, but the intervals between the pairs of lines should be shorter, and the individuals of each pair should be closer together.

The lines of beryllium are not characteristically grouped like those of aluminium and indium; it cannot therefore belong to this series of elements. If we attempt to classify beryllium in a manner which accords with Nilson and Pettersson's views (*Proc. Roy. Soc.*, 1880, vol. xxxi. p. 37), the elements scandium and yttrium, with atomic weights 44 and 89 respectively, must yield spectra typical of the series, and the similarity between the spectra of the two metals, beryllium and scandium, must be exceedingly close. Now Thalén's spectra of scandium and yttrium, though both totally unlike the spectra of any other element, have many characters in common (*Kongl. Svenska Akademicus Handlingar*, vol. xii. p. 4, and *Comptes Rendus*, vol. xci. p. 45); both spectra contain highly characteristic groups of lines in the orange and yellow, the lines or bands degrading towards the red, and the number of lines which have been measured are no fewer than 103 and 90 respectively.

From these two spectra that of beryllium is entirely different, as well in the character and grouping as in the number of the lines. Of the remaining rare earth-metals at present known, cerium is a tetrad, didymium is a pentad, and lanthanum a triad; their spectra are quite dissimilar from that of beryllium. In consideration of these facts it is impossible to classify the spectrum of beryllium along with the spectra of the rare earth-metals of the triad group.

Let us now consider the question of the dyad groups. On the assumption that beryllium has an atomic weight of 9·2, there is no difficulty in placing it at the head of the second series, in which position it stands in the same relation to the sub-groups Mg, Zn, Cd, and Ca, Sr, Ba, that Li occupies with regard to Na, K, Rb, Cs, and Cu, Ag, Hg. Its position will also be similar to that of B and of C in their relation to the triad and tetrad metals. The spectra belonging to Mg, Zn, Cd, have a very definite constitution; they consist of (1) a single line, (2) a pair of lines, (3) three to four groups of triplets, (4) a quadruple group, and (5) a quintuple group of lines. The intervals between the individual lines in their different groupings increase with the increase in the atomic weights of the elements. In fact these spectra present a considerable addition to the body of evidence in support of the view that elements whose atomic weights differ by an approximately constant quantity, and whose chemical character is similar, are truly homologous bodies, or, in other words, are the same kind of matter in different states of condensation (*Journal of the Chemical Society*, September, 1883, p. 390, *Trans.*). Their particles are vibrating in the same manner, but with different velocities. In the spectra of the metals Ca, Sr, Ba, successive pairs of lines are a strong feature, in addition to which there are some other groups in the spectrum of barium. The individuals of each pair are separated by smaller intervals the more refrangible the lines, and by larger intervals the higher the atomic weights. It cannot be said that the spectrum of beryllium is precisely similar in constitution to either of these groups of elements.

There is some slight resemblance in character to the spectrum typical of the calcium group, beryllium having two pairs of lines, the individuals of the first or less refrangible pair being separated by a greater interval than those of the second pair. It is a spectrum analogous to that of lithium, hence it was concluded that beryllium is the first member of a dyad series of elements to which probably calcium, strontium, and barium are more strictly homologous than magnesium, &c. It is to be understood that this is a conclusion drawn from one point of view only, and is open to correction or modification when fresh facts shall have been discovered, but so far the classification of beryllium among the dyads is confirmed and maintained by its position being in harmony with these spectrum observations. The metal is shown to be quite out of place among the triad elements.

SPLENIC FEVER IN THE ARGENTINE REPUBLIC[1]

THE author stated that he did not think any one who had worked much on the subject of splenic fever could doubt that the bacilli which caused that disease were capable of considerable variation in their effects on animals and man. Whether this disease, which is without doubt the one which has been most thoroughly investigated of all zymotic affections, gave any support to the views of Dr. Carpenter was another matter, but there could be no doubt that the *Bacillus anthracis* can be so modified by artificial means that the disease which it produces when introduced into animals, such as sheep and cattle, varies considerably as to duration, amount of fever produced, as well as to its mortality.

That, on the other hand, this bacillus has at least a very strong tendency to retain the characters which it at present presents in Europe is shown by the fact that in the Argentine Republic,—into which the affection was introduced at least thirty years ago, and where the conditions are very different from those which exist in Europe,—we find that the minute organism retains its characteristic form and the properties with which we are so well acquainted in Europe, and that the disease which it produces is practically identical with the European disease. That it should vary in some particulars is perhaps only to be expected, but Dr. Roy preferred leaving that point to be treated of elsewhere and occupying the time at his disposal with an account of the observations which he had made as to the means of protecting from the disease by means of inoculation.

Some six months ago he had been requested by a City company who possess a large tract of land in the Argentine Republic, to pay a visit to their property in order to investigate a disease which was causing much mortality amongst the cattle, sheep, and horses, and which was affecting the *employés* as well to a very serious extent. This disease, he found on arriving at the River Plate, was splenic fever, of which the absence of efficient veterinary surgeons and the general apathy of the owners of stock had prevented the recognition. Having spent some time in studying the characters of the disease, he proceeded to make observations on the best means of protecting the stock by means of inoculation, which work was much facilitated by the liberality of the company (the "Las Cabezas Estancia Company") who gave him "carte blanche" as to the number of animals which he might employ for his experiments. Having previously found, in a small series of observations made in this country in conjunction with Dr. E. Klein, that splenic fever virus from white mice was of the proper strength to protect sheep from the disease, he proceeded in the same lines, employing such animals as were available to produce the inoculating fluid. After a number of animals had been tried, he found that the blood of *Biscachas* (prairie dog) which had died of the disease gave satisfactory results when used to inoculate cattle and horses. It was, however, a little two powerful, as 1 or 2 per cent. of the cattle so inoculated died. The pecuniary loss entailed by this was, however, more than counterbalanced by the arrest of the mortality from the natural affection. With regard to sheep, greater difficulties were encountered, and no animals were found giving a virus sufficiently mitigated to cause only a slight form of the disease with subsequent protection. Unfortunately it was impossible to repeat on a large scale the successful experiments which Dr. Roy and Dr. Klein had made with virus from white mice, these animals not being obtainable. Virus from field-mice and rats did not prove satisfactory.

Under these circumstances the speaker then proceeded to investigate the results obtained by artificial mitigation of the bacilli in the laboratory. He first employed the method of Toussaint, which consists in warming the fluid containing the pathogenic organisms to a temperature of 55° C. for a period varying from a half hour to one hour and a half. It was found possible by this means to diminish the strength of the virus so that it took longer to kill, and by graduating the duration of the heating it is not difficult to obtain a virus which will only kill a small percentage of the animals inoculated. But unfortunately, in weakening the virulence of the organised poison, this process weakens also its power of protecting from a second attack, and it was easy to kill the animals so inoculated by subsequently introducing into their system strong virus which had not been subjected to heat. This method having failed, Dr. Roy proceeded to Buenos Ayres, where, in the laboratory of the "Collegia Nacional," which was kindly placed at his disposal, he manipulated the virus by the method of Pasteur, which consists in cultivating the virus in sterilised chicken broth at a temperature of 42°—43° C. At this temperature the bacilli grow much less readily than at one more nearly approaching blood heat. The bacilli so cultivated diminish in virulence day by day, and after being cultivated for six or eight days no longer caused the death of full-grown sheep, although they still killed lambs and prairie dogs.

Careful experiments with inoculating fluid prepared in this manner showed that with it a slight fever could be induced which suffices to protect, at least for some time, from a second attack of the disease. The same objection, however, which characterises the inoculating fluid prepared by Toussaint's method exists, though to a less extent, with regard to Pasteur's fluid; in the case of the latter as well as the first named, the protecting power is seriously diminished at the same time that the virulence of the bacilli (as indicated by the mortality) is lessened. With care it is possible, however, to prepare a liquid which, while its virulence has been brought sufficiently below the lethal limit to insure that none of the inoculated animals succumb to the inoculation, still retains enough protecting power to enable the sheep to resist the effects of strong virus employed some ten to fifteen days after the first inoculation. Dr. Roy was, therefore, able to confirm the assertions of M. Pasteur regarding the attributes of his inoculating fluid in so far that it is possible effectually to protect sheep from anthrax by its use. Still, it was impossible to overlook the fact that its employment necessitated very careful graduation of the strength of the mitigated virus to the resisting power of the animals inoculated. The speaker did not think that the method was one which was likely to be adopted universally, and he rather looked forward to the general acceptation of some inoculating fluid which had been mitigated by cultivation in the bodies of some animal distinct in species from that which it was desired to protect. In the case of cattle the virus taken from *Biscachas* seemed to protect in all cases, whether the illness produced by the inoculation was mild or severe. It was to be hoped that more extended inquiries would confirm the favourable results obtained by employing the virus from white mice to protect sheep. The speaker stated that he proposed communicating the results of his observations on this subject to the Royal Society at an early date.

SUGGESTIONS FOR FACILITATING THE USE OF A DELICATE BALANCE[1]

IN some experiments with which I have lately been occupied, a coil of insulated wire, traversed by an electric current, was suspended in the balance, and it was a matter of necessity to be able quickly to check the oscillations of the beam, so as to bring the coil into a standard position corresponding to the zero of the pointer. A very simple addition to the apparatus allowed this to be done. The current from a Leclanché cell is led into an auxiliary coil of wire coaxial with the other, and is controlled by a key. When the contact is made, a vertical force acts upon the suspended coil, but ceases as soon as the contact is broken. After a little practice, the beam may be brought to rest at zero at the first or second application of the retarding force.

This control over the oscillations has been found so convenient that I have applied a similar contrivance in the case of ordinary weighings, and my object in the present note is to induce chemists and others experienced in such operations to give it a trial. Two magnets of steel wire, three or four inches long, are attached vertically to the scale pans, and underneath one of them is fixed a coil of insulated wire of perhaps fifty or one hundred turns, and of four or five inches in diameter. The best place for the coil is immediately underneath the bottom of the balance case. It is then pretty near the lower pole of the magnet, and is yet out of the way. The circuit is completed through a Leclanché cell and a common spring contact key, placed in any convenient position. The only precaution required is not to bring other magnets into the neighbourhood of the balance, or, at any rate, not to move them during a set of weighings.

The other point as to which I wish to make a suggestion relates to the time of vibration of the beam. I think that with the view of obtaining a high degree of sensitiveness the vibrations are often made too slow. Now the limit of accuracy depends more upon the smallness of the force which can be relied upon to displace the beam in a definite manner, than upon the magnitude of the displacement so produced. As in other instruments whose operation depends upon similar principles, *e.g.* galvanometers, it is useless to endeavour to increase the sensitiveness by too near an approach to instability, because the effect of casual disturbances is augmented in the same proportion as that of the forces to be estimated. If the time of vibration be halved, the displacement due to a small excess of weight is indeed reduced in the ratio of four to one, but it is not necessarily rendered any more uncertain. The mere diminution in the amount of displacement may be compensated by lengthening the pointer, or by optical magnification of its motions. By the method of mirror reading such magnification may be pushed to almost any extent, but I am dealing at present only with arrangements adapted for ordinary use.

---

[1] Abstract of a paper read at the British Association by Dr. C. S. Roy.

[1] Paper read at the British Association by Lord Rayleigh, F.R.S.

In the balance (by Oertling) that I am now using, the scale divisions are finer than usual, and the motion of the pointer is magnified four or five times without the slightest inconvenience by a lens fixed in the proper position. The pointer being in the same plane as the scale divisions, there is no sensible parallax. In this way the advantage of quick vibrations is combined with easy visibility of the motion due to the smallest weights appreciable by the balance.

To illuminate the scale, the image of a small and distant gas flame is thrown upon it by means of a large plate-glass lens. This artificial illumination is found to be very convenient, as the instrument stands at some distance from a window, but it is not at all called for in consequence of the use of the magnifying lens.

ON THE DEVELOPMENT OF PERIPATUS[1]

AMONG the acquisitions I made during my journey to the West India Island of Trinidad, a rich collection of Peripatus stands in the first rank. This has put me in a position to correct many mistakes, and to contribute a good deal to the knowledge of the histological anatomy of this interesting animal form, as well as especially to follow the process of development from beginning to end. Postponing for the present the anatomy of the adult animal, inasmuch as we have on this subject a good many studies, some of which are very good (for instance, that of Gaffron in *Zool. Beiträge*, edited by Dr. A. Schneider), I shall confine myself to a preliminary notice of the earliest stages of the development of Peripatus, although my investigations have not as yet been brought to a conclusion, nor have I been able to devote any attention to the development of the organs. I do this chiefly because the treatise published by Moseley and Sedgwick from the posthumous notes of Balfour contains some representations of embryos and cross-sections of the same, upon whose accuracy in details I, with my rich and well preserved collection of specimens, and observations on fresh objects, must cast some doubt, and the interpretation of which does not bear investigation. And yet these already serve as evidence for some theoretical explanations of embryonic processes in other groups of animals, which it would be well to avoid in such a case.

I collected in Trinidad over a hundred specimens of *Peripatus Edwardsii*, and a small number of a new species which is distinguished by its size from all those hitherto known, and which may briefly be thus characterised: The females, which are considerably larger than the males, attain a length of 15 cm. and a diameter of 8 mm.; the males grow to a size of about 10 cm. Their colour is a plain reddish brown above, darkening a little towards the middle line of the back, and growing pale a little towards the sides. The head, or, more correctly, the forehead, as well as the antennæ, is black, and marked off on the dorsal side by a light yellow necklace, which is often slightly interrupted in the middle, from the rest of the body. The under side is of a dark flesh colour. This species is especially characterised by possessing forty-one to forty-two pairs of feet, which is the highest recorded number, and a number which differs greatly from that of all other species. I call this new species *Peripatus torquatus*.

The ovaries are two small, elongated bodies, which are generally united along their whole length, and so appear as a narrow, spindle-shaped body, which is connected by one or often by two delicate muscular threads to the body wall. The ovaries are prolonged into the two horns of the uterus, which, each forming a bow with several curves, unite immediately before reaching the genital pore to form a very short vagina. At the point where the ovaries pass over into the uterus is situated a small, nipple-shaped gland and a spherical receptaculum seminis, the orifice of which every egg has to pass before it can enter the uterus. Now as a large number of embryos, from the "just furrowed" egg to the matured young, are always found in the uterus, it is very probable that each female Peripatus is only fertilised once.

The eggs of Peripatus contain no yolk, and seeing that in spite of this an animal of half the length that it attains when adult develops itself in the uterus out of a small egg whose diameter is about 0·04 mm., there must be some quite peculiar means for its nutrition, and this is the case to the most astonishing extent and in the most surprising manner.

As soon as the fertilised egg enters the thin portion of the uterus, a small enlargement takes place in its lumen, which is very narrow and is surrounded with very deep cylinder epithelia. Simultaneously with this the epithelium cells mass themselves a little together; the furrowed egg settles upon the epithelium, and immediately the lumen widens a good deal by the epithelial cells of the uterus becoming very depressed at that spot; so flattened do they become that they form a very thin pavement-epithelium, whereas before and behind the "breeding-nidus" (*Bruthöle*) an embankment is formed by the thickening of the connective tissue of the uterine walls, so as nearly to fill up the uterine canal.

In this stage we find a hemispherical mass of homologous cells attached by a broad basis to the extraordinarily thin lining of the uterine cavity, a lining which has been formed out of the two cells that originally surrounded the egg. Presently a small depression develops in this hemispherical mass, and now the embryo forms something like the half of a hollow sphere, still consisting of but a few cells. Through the multiplication of these the hemisphere and the cavity in it become a little larger, and now a difference is perceptible between the cells of the embryo which are situated immediately upon the uterine epithelium and the rest. The former, which I shall for brevity's sake here call basal cells, have a long, narrow, and very compact nucleus, whereas the others have a large, circular, granular nucleus. The basal cells multiply, and in doing so close the opening of the hemisphere, and form a layer which, lying between the embryo and the uterine epithelium, fastens the former to the latter. In the meantime the cells of the hemispherical mass have also multiplied to such a degree that the side looking towards the lumen of the uterus appears thickened by the cells mutually displacing each other.

In this stage the whole condition of the embryo resembles that of a flattened hollow sphere whose free wall has been thickened; the longer diameter is 0·09 mm., and the lesser 0·07mm. The basal cells of the embryo now spread themselves out a little, a few isolated ones come out from under the embryo, and thus enlarge the basis of attachment—they form an *embryonic placenta*. From them is also developed a very delicate membrane, which becomes closely applied to the uterine epithelium, and envelops the embryo—it may be shortly designated as *amnion*.

In the meanwhile changes are also going on in the uterus; the epithelium of the "breeding-nidus" has become a little thicker, the nuclei have increased in number, and a number of small dark brown pigment granules have developed and collected in the protoplasm of the flat cells, which for a long time mark off sharply the uterine epithelium from the embryonic portions.

The basal cells now multiply to a remarkable extent, partly so as to increase the size of the placenta, and partly in a direction perpendicular to it, forming a solid stalk upon which the embryo is pushed out free into the lumen of the "breeding-nidus." The whole now forms a pyriform mass; the little head of the pear, the actual embryo, is, however, now no longer hollow; cells have been thrust in from the side furthest away from the stalk, which have filled up the whole "furrow cavity"; a sharp limit, however, is visible between them and the ectoderm at every point except the place where they have been invaginated; this point, which is comparable to the blastopore of other embryos, persists for a long time as the spot where material for the inner germinal layers is being continually provided by invagination, and is still demonstrable in embryos in which the form of Peripatus has long since been recognisable.

As soon as the "furrow cavity" has been filled up in the manner that has been described, a new cavity develops by fission in the central mass of cells. This is the definite visceral cavity. It develops by the embryo becoming composed of two layers (ectoderm and entoderm) in the half that is nearest to the stalk, whereas a thick prominence in which no differentiation can be made out, lies on the side furthest from the stalk. One must, however, regard its innermost cell layer as belonging to the entoderm, which also is continued into it.

---

[1] Translated from a notice, by Dr. J. von Kennel of Würzburg, in the *Zoologischer Anzeiger* for October 8, 1883.

While these changes have been taking place in the embryo, the "breeding-nidus" has increased considerably in size, the uterine epithelium has become thicker, and consists of a finely granular mass of protoplasm in which large round nuclei are found, and often lie in several layers one on top of another; cell boundaries are no longer recognisable, and the pigment granules, which are disappearing, still form a narrow border towards the lumen of the uterus. Before and behind the breeding-nidus is almost altogether closed by great thickenings of the uterine walls. In the region of the breeding-nidus, however, there is a fissure in the connective tissue wall of the uterus which is probably a blood space.

The next stage in the development of the embryo may be shortly characterised as the mushroom form; the embryo becomes more clearly marked off from its stalk, and expands in all directions, but most of all in the direction of the longitudinal axis of the uterus, and now for the first time a bilateral symmetry can with certainty be made out; the whole embryo resembles a mushroom with a thick stalk; the pileus is oval, as seen from above, and is a little broader at one end than at the other, and on the surface, towards the narrower end, is to be seen a shallow depression, which is limited towards the broader end by a slight prominence. This depression corresponds to the spot where the meso- and entoderms have been invaginated. There is as yet no opening to connect the visceral cavity with the outer world. The broader end of the embryo is the head end, the stalk side the back, the surface that projects into the lumen of the uterus the future ventral surface. In this stage a multiple layer of cells has already freed itself from the ectoderm, in front of the place where the invagination took place, and it lies, passing over behind into the undifferentiated cell-mass, between the ecto- and entoderm, but is marked off from both of them by a distinct boundary.

Now while the embryo increases in length, more and more cells press in from the ectoderm at the spot that has been indicated, and specialise themselves towards the front into a real mesoderm, which, however, at first, and for a long time afterwards, occupies only the ventral aspect and also the lateral regions between ectoderm and entoderm, where it of course multiplies independently.

In the meanwhile the thickening of the uterine epithelium has gone on; it now forms a ring, which surrounds three-quarters of the circumference of the breeding-nidus, and which as a broad zone divides the breeding-nidus into two halves, where, by the way, the epithelium has been thickened to a considerable though a less degree; the pigment granules have now disappeared, the placenta has become very large, and the amnion, which has attained a high degree of development, and which consists of numerous large cells with large nuclei, lies closely applied to the uterine epithelium.

It is only when the embryo has still further increased in length, the part posterior to the stalk increasing very quickly in size, that the anus and mouth are formed, but not from a common opening, the blastopore of Balfour. The anus develops as a small fissure in the median line upon the prominence in front of the spot where the invagination has taken place; but the mouth develops far further forwards as an invagination of the ectoderm, consisting of only very few cells. This invagination has an inclination obliquely from behind forwards as it proceeds, and reaches the intestine, dividing its epithelium at the point of junction. This mouth invagination has as yet no lumen; this makes its appearance later, when the embryo already shows its segmentation plainly.

The first trace of this segmentation is the appearance of a cavity on each side in the oldest portions of the mesoderm, *i.e.* in the anterior extremity of the embryo, which splits the mesoderm plates into an inner membrane adjoining the intestine, and an outer one adjoining the ectoderm. These, however, are still connected to each other dorsally and ventrally. Soon afterwards a second pair of similar cavities develops behind, and so on from before backwards. These cavities that appear in segments, and which in their appearance closely resemble the original segmental formation of a vertebrate animal, are the first rudiments of the body cavity. The different structures that develop out of its walls cannot be made out till later. With the exception of the further growth of the posterior end of the embryo, which soon curves itself, rolls itself up spirally, and finally forms manifold loops, and of the progress of the segmentation, and of the corresponding formation of cavities in the mesoderm, no changes take place in the interior of the embryo. Embryos of *P. Edwardsii* of 1–1·5 mm. length always present the same appearance on cross-section: an ectoderm slightly thickened on the ventral aspect, an extraordinarily thin entoderm, and between them on each side a pocket of mesoderm, whose walls touch each other in the ventral median line, and which in well-preserved embryos always are closely applied to the ectoderm, as well as to the entoderm, but which always present a sharply-defined boundary line. The anus is still nothing more than a narrow longitudinal fissure; the mouth has at last opened. Behind the anus is situated the depression, with the place where invagination has taken place.

Externally, on the other hand, a distinct segmentation of the body has taken place corresponding to the cavities in the mesoderm; the anterior segment (head segment) exceeds all the others in size; it consists of two symmetrical, spherical halves, to which the other segments are connected posteriorly; the ventral aspect of the head segment contains the mouth opening. I remark here that the mouth and anal opening that have been mentioned must be regarded as primary in Peripatus; the latter closes at a later stage to make room for a later-developing structure, and the former is thrust in further by a new invagination of the ectoderm, and becomes converted into the œsophageal opening of the intestine. (These two observations require to be checked, and I shall have to do so by examining other embryos.) Each segment carries on each side a prominence which is the rudiment of the limbs that are developed later. The first pair of limbs is surrounded by a number of secondary papillæ, and is drawn into a wide mouth cavity to be utilised as a jaw; the second pair gives the papillæ on whose apices the large slime glands afterwards have their orifices. The tentacles are simply dorsal continuations or prolongations of both head cavities. Now at last, after the embryo has attained its full complement of segments, the first appearance of the nervous system can be made out as a paired ventral thickening of the ectoderm, which, soon separating itself from the ectoderm, extends in two separate threads from one end of the body to the other, only united by the brain, which has been developed in a similar manner in the head. The embryo itself, until it develops a definite gullet, is intimately connected by its ectoderm, by means of the placenta with the maternal organism, and receives its nutriment through its dorsal stalk, which can be quite properly characterised as a navel-string, and which belongs to the first body segment. As soon, however, as it can swallow by help of its gullet, this connection is loosened, and the embryo now eats the food that is provided by the extraordinarily thickened uterine epithelium, which is rich in protoplasmic materials. At any rate, from that time forward coagulated protoplasm is always to be found in the intestine of the embryo, which was previously always empty.

This is, in a few words, an abstract of the most important results of my investigations up to date, which have been made upon something like a hundred young embryos. I here abstain for the sake of brevity from all discussion, but must, however, call attention to the fact how little Balfour's illustrations and the descriptions of the editors agree with the facts as they are here given. I hope it will not be long before I shall be able to lay before my fellow-workers my investigations, which I hope soon to complete, of these interesting and exceedingly anomalous phenomena of embryonic development, accompanied by numerous illustrations.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—By a mistake last week the stipend of the Professorship of Botany was given as 500*l.* instead of 700*l.* with a residence rent free. An election will take place in the course of Hilary term. The duty of the professor is to lecture and give instruction in botany. He will also have charge and supervision of the Botanical Garden and of the botanical collections belonging to the University; and it will be part of his duty to make such gardens and collections accessible to and available for the instruction of students attending his lectures. Candidates are requested to send to the

Registrar of the University their application, and also any documents which they may wish to submit to the electors, on or before Saturday, January 26, 1884.

The Professorship of Rural Economy—now separated from that of Botany—will be filled up in December. Candidates are requested to send to the Registrar of the University their applications, and any documents they may wish to submit to the electors, on or before Monday, December 10, 1883. According to the regulations sanctioned by the Court of Chancery, the Sibthorpian Professor of Rural Economy shall lecture and give instruction on the scientific principles of agriculture and forestry. He shall be entitled to the emolument of 200*l.* derived from the benefaction of Dr. John Sibthorp, Doctor of Medicine, and assigned to the professorship. The professor holds his office for a period of three years from election, and no longer. He may be re-elected for a second period of three years, and no longer; but no professor shall hold the professorship for more than six years consecutively. The professor will have the use of the garden appropriated for making experiments on the subjects of his professorship. The professor shall give not less than twelve lectures in the course of the academical year, in full term, and not more than two in any one week.

Cambridge.—The following are the speeches made to the Senate of the University by the Public Orator (Mr. J. E. Sandys) in presenting Professors Foster and Macalister for the complete degree of M.A. *honoris causâ*, on November 8:—

"Dignissime domine, domine procancellarie et tota Academia: In hoc ipso loco, duodecim abhinc annos, unum e Collegii maximi Prælectoribus auspiciis optimis titulo vestro honorifico exornastis. Hodie eundem, tot annorum usu et experientia spectatum probatumque, et Academiæ totius Professoribus merito adscriptum, senatus nostri in ordinem honoris causa adsciscimus. Quantum interim, hujus præsertim laboribus, inter alumnos nostros creverit vigueritque physiologiæ studium, vosmet ipsi omnes animo grato recordamini. Ut animantium in corporibus ex ipso corde, velut e fonte quodam, salutares illi sanguinis rivi per membra omnia fluunt refluuntque; non aliter corporis Academici in partes quam plurimas ex hoc fonte scientiæ flumina effluxisse atque inde rursus redundasse dixerim. Tali e fonte quot alumnis vires novæ redditæ sunt: quotiens ex alumnis rivuli fontem ipsum denuo auxerunt! E discipulis vero tam multis cum magistro tanto feliciter consociatis, plurimos adhuc superesse, nonnullos etiam adesse hodie gaudemus; unum illum non sine lacrimis desideramus qui nascentis vitæ primordiis hujus auxilio sagacissime investigatis, nuper inter Alpium culmina, in ipso ætatis flore, morte immatura e nobis est abreptus. Talium filiorum progenies Matri Almæ indies nova succrescat: magistrorum talium accesionibus et Professorem et Senatorum ordo identidem nobis augeatur!

"Vobis præsento Collegii sacrosanctæ Trinitatis socium, Physiologiæ Professorem illustrem, Michaelem Foster."

"In Professoribus novis vestro omnium nomine salutandis, fato quodam iniquo successoris laudes decessoris desideria nonnunquam aliquatenus imminui videntur. Hodie vero ornat adhuc Professorum ordinem eloquentissimus ille Anatomiæ Professor quem diu sumus admirati. Integro igitur sinceroque gaudio Professorem illum salvere jubemus, quem Caledonia Hiberniæ quondam donavit, Hibernia Britanniæ nuper reddidit. Salutamus virum qui corporis humani scientiam interiorem, antiquissimum illud atque regium (uti nuper audivimus) scribendi argumentum, quasi propriam provinciam penitus exploravit; qui ne his quidem finibus contentus, sed etiam in alias rerum naturæ regiones egressus, non modo de zoologia et de comparativa quæ dicitur anatomia egregie meritus est, sed geologiæ quoque operam singularem impendit, petrographiæ præsertim recentiores, progressus curiositate minuta perscrutatus. Idem et litterarum amore et linguarum peritia insignis, inter rerum antiquarum monumenta ne hieroglyphica neglexit, neque historiam ecclesiasticam intactam reliquit. Ergo non uni tantum Collegio sed toti Academiæ gratum est, virum tot tantisque animi dotibus instructum, societati illi tam cito esse adscriptum, cui medicinæ studia commendavit olim vir et de litteris antiquis et de scientiis recentioribus præclare meritus, Thomas Linacre.

"Vobis præsento Collegii Divi Johannis socium, Anatomiæ Professorem insignem, Alexandrum Macalister."

The allusions to the growth of the physiological school, to the loss of Prof. F. M. Balfour, to Prof. Macalister's inaugural lecture with its happy antiquarian illustrations, and his speedy enrolment as a Fellow of St. John's, were heartily taken up by the members of the Senate and the undergraduates present.

The Special Board for Medicine publish for the guidance of students proceeding to medical and surgical degrees the following schedule defining the range of the examination in elementary biology under the regulations which come into effect on the first day of January, 1884 (Grace, November 15, 1883). The examination in elementary biology will have reference to (1) the fundamental facts and laws of the morphology, histology, physiology, and life-history of plants as illustrated by the following types: *Saccharomyces*, *Protococcus*, *Mucor*, *Spirogyra*, *Chara* or *Nitella*, a fern, *Pinus*, and an angiospermous flowering plant; (2) the fundamental facts and laws of animal morphology, as illustrated by the following types: *Amœba*, *Paramœcium* or *Vorticella*, *Hydra*, *Lumbricus*, *Astacus*, *Anodon*, *Amphioxus*, *Scyllium*, *Rana*, *Lepus*. Under the head of vegetable physiology the student will not be expected to deal with special questions relating to the more highly differentiated flowering plants. He will be expected to show a practical knowledge of the general structure of each of the animal types above specified, and an elementary knowledge of the chief biological laws which the structural phenomena illustrate. He will also be expected to show an elementary knowledge of the general developmental history of *Amphioxus* and of *Rana*. He will not be expected to deal with purely physiological details.

The subject announced for the next Adams Prize to be adjudged in 1885, is as follows: Investigate the laws governing the interaction of cyclones and anticyclones on the earth's surface. In order to give precision to this, the following suggestions are given to the examiners:—An infinite plane has surface density $\frac{g}{2\pi}$ (where g is gravity); on one side of it is air in equilibrium, the density of which must diminish according to the barometric law as we recede from the plane. The system revolves as a rigid body, about an axis perpendicular to the plane, with a constant angular velocity ω. If one or more vortices, with a revolution either consentaneous with ω (cyclones), or adverse thereto (anticyclones), be established in the air, investigate their motions. It may be well to consider the axes of the vortices as either straight or curved, and perpendicular or inclined to the plane. If possible, pass to the case in which the vortices exist in the atmosphere surrounding a rotating globe.

The Rev. H. W. Watson has been approved for the degree of Sc.D.—Prof. Darwin is arranging to give a course of practical teaching in astronomy with the instruments under his charge. Next term Mr. H. H. Turner of Trinity College will undertake this course.—The General Board of Studies, in re-issuing its recommendations as to Readers, Demonstrators, &c., has asked that power be given to the Museums and Lecture Rooms Syndicate to obtain plans for a foundry for the Department of Mechanism, for buildings for Botany, and for additional buildings for Comparative Anatomy and Physiology.—It is recommended that a Curator of the Museum of General and Local Archæology be appointed, at a salary of 100*l.* per annum.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, vol. cxvi. No. 694, October, 1883.—The commercial and dynamic efficiencies of steam-engines, by Prof. R. H. Thurston. In this paper there are calculated the ratio of expansion to furnish power most economically, the maximum efficiency of a given plant, and maximum efficiency of fluid, when such data are taken into account, as total annual cost of steam, and total annual cost of all items variable with size of steam-cylinder.—Mr. R. Grimshaw, in a paper on the steam-engine indicator as a detector of lost motion, describes the use of the indicator to pick out defective setting of cranks, cross-heads, &c.—The next three articles are on the water supply of cities in ancient times, on oil-dressed belting, and a report on the pressure-governed gas-meter and burner.—The address by Prof. Rowland, entitled "A Plea for Pure Science," lately reprinted in Nature, is also reproduced *in extenso*.

Annalen der Physik und Chemie, xxii. No. 10, contains a long memoir by Professors Sohncke and Wangerin on interference phenomena obtained with thin and especially with wedge-shaped laminæ. The article will be continued in the next number.—On the changes of volume of metals and alloys on melting, by Prof. Eilhard Wiedemann. The metals were cast in thin rods, then dropped into a nearly-fitting glass tube, ending into a capillary. The wide end was sealed, and a dilatometric fluid such as oil introduced. The conclusions arrived at are that tin, soft solder, and probably also lead, expand on melting; but bismuth contracts. Many observations were made on alloys of bismuth and lead.—On the liquefaction of oxygen, nitrogen, and carbonic oxide, by S. von Wroblewski and C. Olszewski. Intense cold was obtained by evaporation, under reduced pressure, of liquefied ethylene in an apparatus modified from that of Cailletet. Temperatures were measured by a hydrogen pressure-thermometer. Oxygen proved to be liquefiable at temperatures varying from – 129°·6 to – 135°·8 C., under pressures varying from 27·02 to 22·2 atmospheres. The liquefaction of nitrogen and of carbonic oxide proved more difficult, and was not accomplished at a temperature of – 136° C., even under a pressure of 150 atmospheres, though a sudden release of pressure produced a temporary mist of condensed spherules, and a slower release of pressure yielded a deposit of liquid with a distinct meniscus. Liquefied nitrogen and liquefied carbonic oxide are both colourless and transparent.—On the internal friction of certain solutions, and on the viscosity of water at different temperatures, by K. F. Slotte. The results confirm those previously obtained by Rosencrantz and Poiseulle.—On a lecture apparatus for demonstrating Poiseulle's law, by W. C. Röntgen.—On the deduction of the crystal systems from the theory of elasticity, by H. Aron; a mathematical discussion of the possible cases arising from the position of planes of symmetry, proving that no others than the recognised six systems of crystals can exist.—On the properties of benzine as an insulator and as a substance exhibiting electric reaction, by H. Hertz. *Pure* benzine appears to be remarkably good as an insulator and remarkably free from reaction effects.—On the influence of galvanic polarisation on friction, by K. Waitz. Treats of the phenomenon discovered by Edison, and recently examined by K. R. Koch.—On the properties of calc-spar in the homogeneous magnetic field, by Fr. Stenger.—Notes on a photometric apparatus, by Leonhard Weber.—On "the Exhibition of the Treatise on Light" of Ibn al Haitam, by E. Wiedemann.—On the Cologne air-pump of the year 1641, a historical notice by Dr. G. Berthold.—Remarks on the memoir of Herr Christiansen, "Researches on Heat-Conductivity," by A. Winkelmann.

Atti of the Royal Academy dei Lincei, July 12-15, 1883.—Obituary notice of William Spottiswoode.—Two communications from Signor Tacchini on the observations made by him at Caroline Island during the solar eclipse of May 6, 1883.—On the average variation in tension of the atmospheric aqueous vapour according to latitude and elevation in Italy, by A. Lugli.—Meteorological observations at the Royal Observatory of the Campidoglio for the months of June and July.—Most of the present number is occupied with the new reforms and statutes of the Academy, whose constitution has recently been remodelled. There are also long inventories of the works of art, furniture, and fixtures of the Palazzo Corsini, which has been purchased as the future home of the Academy.

Rivista Scientifico Industriale, Florence, September 15-30.—The total eclipse of May 6. Results of the observations of Tacchini, Janssen, and others, in Caroline Island.—Eclipses and terrestrial magnetism, by P. Denza. All connection is denied between eclipses and magnetic phenomena.—On the compressibility of water, by S. Pagliani and G. Vicentini.—A new electrodynamometer, by Prof. Bellati.—On the deformation detected by Gouy in polarised electrodes, by A. Volta.—An improved reversible magnetico-electric machine, by M. Delaurier.—Anatomical description of two extremely rare birds (*Somateria mollissima* and *Phalaropus fulicarius*) preserved in the Civic Museum of Venice, by P. A. Ninni.—On the fossil vertebrates of the Miocene formations in the Venetian Alps, by Baron Achille de Zigno.—On the fossil gastropods, cephalopods, and corals of the lower titonic formations of Sicily, by Dr. G. de Stefano.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, November 15.—Dr. Perkin, F.R.S., president, in the chair.—It was announced that a ballot would take place at the next meeting (Dec. 6).—The following papers were read:—On the estimation of starch, by C. O'Sullivan. The method may be briefly described as follows:—About five grms. of the finely ground grain are successively extracted with ether, alcohol (sp. gr. 0·90), and water at 35° to 38°. Fat, sugar, albuminoids, amylams, &c., are thus got rid of. The starch in the washed residue is gelatinised by boiling with water, cooled to 62°, about 0·03 grm. diatase (prepared by precipitating a cold, aqueous extract of malt with alcohol) added; the starch is thus converted entirely into maltose and dextrin, and by a quantitative determination of these two products the starch originally present can be calculated. The author states, as the result of his experience with the method, that the difference in results obtained by any two observers need not exceed 0·5 per cent. of the total starch—On the illuminating power of ethylene when burnt with non-luminous combustible gases, by P. F. Frankland. The author summarises his results as follows:—Pure ethylene burnt at the rate of five cubic feet per hour from a Referees Argand burner, emits a light of 68·5 standard candles; the illuminating power of equal volumes of mixtures of ethylene with either hydrogen, carbon monoxide, or marsh gas is less than that of pure ethylene; when such mixtures contain 60 per cent. of ethylene or more, the illuminating power of the mixture is but slightly affected by the nature of the diluent; in mixtures containing less than 60 per cent. of ethylene, the illuminating power is the highest when marsh gas, and lowest when carbon monoxide, is the diluent.—On the products of decomposition of aqueous solutions of ammonium nitrite, by G. S. Johnson. The nitrogen evolved from alkaline solutions of ammonium nitrite contains no oxides of nitrogen; nitrogen is evolved from aqueous solutions below 100°; by adding crystallised cupric chloride, a continuous evolution of pure nitrogen takes place in the cold. When solutions are acid, the nitrogen may contain 4 per cent. of nitric oxide. About 2 per cent. of the nitrogen evolved by the cupric chloride is stated by the author to possess peculiarly active properties, and forms ammonia when passed with hydrogen over spongy platinum.—On the estimation of iron by standard potassium bichromate, by E. B. Schmidt. The author recommends the above process, but states that zinc should not be used to reduce the iron, as it interferes with the end reaction with potassium ferricyanide. He prefers Kessler's method of reduction with stannous chloride.

Western Microscopical Club, November 5.—Mr. W. Crookes gave a lecture on "Recent Discoveries in High Vacua." He illustrated his theme with a series of brilliant and interesting experiments. The effects were produced by a large electric coil, having sixty miles of secondary wire, and worked by two cells of a storage-battery. The coil, when attached to its full complement of thirty cells, would give a spark in air of twenty-four inches. "High vacua" were defined as those ranging from above the 1/1000 to the 1/100,000,000 of an atmosphere. Air and all gases are conceived to consist of myriads of excessively minute molecules, which in the ordinary state vibrate with enormous velocity; but being crowded together in that condition their extent of vibration is impeded by each other, and is, in fact, limited to a path of only 1/10,000 of a millimetre. When, as in a partial vacuum, there are fewer of these molecules, they have more room in which to vibrate, and hence their "mean length of path" is increased. Under the influence of electricity these molecules are driven in straight lines from the negative pole. In a comparatively low vacuum, on the passage of an electric current, the residual air assumes a stratified condition, showing alternate light and dark bands. The width of the dark bands marks the length of the excursions of the molecules. Further exhaustion increases the width of these bands, so that in a vacuum of 1/1,000,000 of an atmosphere the free path of the molecules was seen to extend to about four inches. By means of an exhausted V-shaped tube it was shown that these molecules are driven from the negative pole in straight lines, and hence cannot turn a corner. First one limb of the V, then the other, was connected with the negative pole of the coil, with the result that each in turn was in darkness. In another vacuum-tube a concave negative pole was fixed; the molecules were driven normally from this concave surface, and, meeting the cylindrical surface of the glass inclosure, were thrown into beautiful caustic curves. That these molecules, under the influence of electricity, possessed mechanical force was shown by causing them to impinge on the vanes of a radiometer, when a rapid rotation took place. On reversing the current, the direction of rotation was also reversed. That this was not due merely to the passage of an electric current was shown by a vacuum-tube containing a small, horizontal "water-wheel." Its upper and lower floats being struck equally by the radiant matter, no motion took place; but on diverting the flow of radiant molecules by means of the external application of a magnet, the molecules were caused to strike the upper floats only, when revolution took place. By reversing the magnet, the path of the molecules was diverted so as to strike the lower floats, and thus to reverse the rotation. Radiant molecules are not attracted by one pole of a magnet and repelled by the other, but tend to rotate round the north pole in one direction and round the south pole in the opposite direction. Hence, with a horseshoe magnet, they are deflected in a line at right angles to the line that joins the two poles. The mechanical effect of the impact of these radiant molecules was further shown by converging them by means of a concave negative pole to a focus in which was a small bundle of platinum wires. These wires were rapidly raised to a white heat by the vigorous though inaudible bombardment. Further, the impact of radiant molecules on certain bodies produces phosphorescent light; thus they give to potash-glass a green and to lead-glass a blue tinge. If in an exhausted tube an obstacle, such as a piece of mica in the shape of a cross, be set up, a dark shadow of it is thrown on the positive end of the tube, the part surrounding the shadow being rendered phosphorescent by the impact of the molecules. On suddenly removing the obstacle, the part that was in shadow glows brighter than in surrounding luminous space. This effect is due to the molecules acting suddenly on a new and, as it were, untired surface.

CAMBRIDGE

Philosophical Society, October 29.—The following officers for the ensuing year were elected:—President, Mr. Glaisher; Vice-Presidents: Prof. Cayley, Prof. Stokes, Lord Rayleigh; Treasurer, Mr. J. W. Clark; Secretaries: Mr. Trotter, Mr. Glazebrook, Mr. Vines; New Members of Council: Prof Humphry, Prof. Babington, Prof. Adams, Prof. Newton, Mr. F. Darwin, Mr. Shaw, Mr. Sedgwick.—The following papers were communicated to the Society:—On the effect of viscosity upon the tides, by Rev. Osmond Fisher.—Note on Mr. Larmor's communication on "Critical Equilibrium," by Mr. Greenhill.—On some general equations which include the equations of hydrodynamics, by Mr. M. J. M. Hill.

EDINBURGH

Mathematical Society, November 9.—Mr. J. S. Mackay, F.R.S.E., in the chair.—The opening address of the session was delivered by Prof. Tait, who chose for his subject "Listing's Topologie."—The office-bearers elected were:—President, Thomas Muir, F.R.S.E.; Vice-President, A. J. G. Barclay; Secretary and Treasurer, A. Y. Fraser; Committee: R. E. Allardice, William Peddie, Robert Robertson, David Traill, B.Sc.

PARIS

Academy of Sciences, November 12.—M. Blanchard, president, in the chair.—On the velocities acquired in the interior of a vessel by the diverse elements of a fluid during its discharge through a lower orifice, and on the simple means possible to be employed in determining very approximately the numerical residuums of slightly converging double series, by MM. de Saint-Venant and Flamant.—Extract from a letter addressed to M. Daubrée by M. Nordenskjöld on the results of his recent expedition to Greenland.—On a tribasic oxalate of alumina, by M. Mathieu-Plessy.—Note on the letter communicated to the Academy by M. Martial, Captain of the *Romanche*, on his return from Tierra del Fuego and neighbouring waters, by M. Alph. Milne-Edwards. Soundings and dredgings were taken at depths of 600 metres; a careful study was made of the fauna and flora on the mainland, as well as of the Fuegian aborigines, and 167 cases of collections were brought back, including two skeletons of whales, and several living specimens of animals and plants. On his return M. Martial determined the presence of a deep trough about the twentieth meridian south of the equator, 7370 metres deep, near the ridge of submarine banks discovered by the *Challenger* and *Gazelle*.—Observations on the Pons-Brooks comet made at the Observatory of Nice (Gautier-Eichens equatorial), and comparison with MM. Schulhof and Bossert's ephemerides, by M. Perrotin.—On certain astronomical formulas of Hansen and Tisserand, by M. P. Appell.—On the asymptotic lines of wave surfaces, by M. G. Darboux.—On the functions of two independent variables rendered invariable by the substitutions of a discontinued group, by M. E. Picard.—Note on the nature of an algebraic relation between two uniform functions of an analytical point (x, y), by M. E. Goursat.—On an algebraic problem in the theory of elimination, by M. Cyparissos Stéphanos.—A description of the differential pyrometer patented in February, 1882, by M. E. H. Amagat.—On an optical photometer, by M. L. Simonoff.—On the measurement of electromotor forces (two illustrations), by M. E. Reynier.—On an electric sounding apparatus for great depths (four illustrations), by M. E. de la Croix.—On a rapid method for determining the work absorbed or produced by a dynamo-electric machine, by M. Pierre Picard.—On a new series of combinations of titanium, by M. A. Piccini.—Qualitative research and quantitative analysis of zinc and lead in iron ores, by M. A. Deros.—On the formation of considerable quantities of alcohol in the fermentation of bread stuffs, by M. V. Marcano.—Determination of the causes tending to diminish the susceptibility of certain regions of the organism to the virus of bacterian or symptomatic charbon, transforming a fatal into a prophylactic inoculation, by MM. Arloing, Cornevin, and Thomas.—On the source of the imperfectly-oxydised sulphur present in urine, by MM. R. Lépine and G. Guérin.—On the development of the branchia of cephalopods, by M. L. Joubin.—On the functions of the renal sac in heteropods, by M. L. Joliet.—Remarks on the *Crocodilus robustus*, Vaill. and Grand., of Madagascar, by M. L. Vaillant.—On the osmotic force of diluted solutions, by M. Hugo de Vries.—On the interpretation of an experiment by Hales touching the function of vegetable vessels, by M. J. Vesque.—Note on the direct observation of the movement of water in plants, by M. G. Capus.—Remarks on the saccharoid and serpentine limestones of the northern slopes of the Pyrenees, by M. Dieulafait.—On the causes of abnormal winters (five illustrations), by M. L. Teisserenc de Bort.—The election was reported of M. Charcot in place of M. Cloquet in the Section of Medicine and Surgery.

SCIENTIFIC WORTHIES

XXIII.—SIR CHARLES WILLIAM SIEMENS,[1] BORN APRIL 4, 1823; DIED NOVEMBER 19, 1883

THE death of Sir William Siemens, coming as it did so suddenly and unexpectedly, has been felt as a severe blow and grief through a far wider circle than that of his personal friends. His work for the last five or six years has interested the general public to a degree that has perhaps never before been the lot of any man devoted to science as he has been. Not only the people of his adopted country, England, but the larger public of the whole civilised world, have been deeply interested in the electric lighting, the electric transmission of power, the electric railways, the regenerative gas furnaces, and the conversion of fuel into gas to feed them, and the prospect of smoke abatement by this mode of dealing with coal, and the improvements it has helped to make in the manufacture of steel, in all of which they have recognised Sir William Siemens as an originator, a devoted worker, and a friend. The Portrush and Bushmills electric tramway in the north of Ireland, one of the most splendid and interesting of his achievements, now carries passengers on a six and a half miles line of steep gradients and sharp curves, at a good ten miles an hour, solely by water power of the River Bush, driving, through turbines, a 250 volt Siemens dynamo at a distance of seven and a half miles from the Portrush end of the line. Just two months before his death he was present, and the writer of this article had the great pleasure of being present with him, at the formal opening to the public by the Lord-Lieutenant of Ireland, Earl Spencer, of this transcendent gift of science to mankind. His death is mourned irreparable loss, and the thought that advances in so many lines of beneficent progress, carried on by his untiring activity and his splendid zeal, are so suddenly stopped has caused most grievous disappointment.

William Siemens had the great characteristic common to all men who have left their mark on the world, the *ingenium*, in which thought leads to instant action. When he was only twenty years old he came to England with his brother Werner, to realise an invention for electro-gilding; and, persevering through the complication of difficulties naturally met with by young men in a strange land, with little knowledge of its language, they succeeded in proving the usefulness of their invention, and getting it carried into practical effect through the wise and kindly appreciation of Mr. Elkington. Encouraged by this success, William Siemens returned a ear later with his chronometric governor, an invention remarkable beauty and ingenuity, in which, by the motion of a pivoted framework carrying an idle wheel geared to bevel wheels on two shafts in line, or geared to the outer and inner circumferences of concentric wheels, ating in opposite directions on coaxial shafts, the move- of one wheel is caused to keep time with that of the er. We believe that although the invention was not a commercial success, and is not generally known in this country as practically realised except in its application to regulate the motions of chronoscopic instruments in the Royal Observatory of Greenwich, it may yet be destined to have large practical applications in engineering.

One of William Siemens's early inventions was his water-meter, which exactly met an important practical requirement, and has had a splendid thirty years' success. It realised curiously subtle hydraulic principles, which, even irrespectively of the practical value of the instrument, may interest readers of NATURE. Imagine a Barker's mill running absolutely unresisted. The discharged water must have approximately zero absolute velocity on leaving the nozzles; in other words, its velocity relatively to the nozzles must be approximately equal to the contrary absolute velocity of the nozzles. Hence the machine will rotate in simple proportion to the quantity of water passing through it. By an extension of similar considerations it is easy to prove that if the wheel, instead of being unresisted, is resisted by a force exactly proportional to the square of its angular velocity, its velocity must still be proportional to the quantity of water passing through it per unit of time. Thus, provided this law of resistance is maintained, the whole angle turned through by the wheel measures the whole quantity of water that has passed. Now think of the difficulties which Siemens had to overcome to realise this principle. What we have roughly called a Barker's mill must be completely inclosed in the supply water-pipes, its nozzles discharging into water, not into air. It must be of very small dimensions to be convenient for practice, and its bearings must be kept oiled to secure, not only that it may not be injured by the wear of running for years, but also that the constant frictional force of solid rubbing on solid may be as nothing compared to the resistance, proportional to the square of the velocity, exerted by the circumambient liquid upon a wheel with sharp edged vanes rotating in it. After a few years of trials, difficulty after difficulty was overcome, and the instrument did its work with the accuracy and convenience which met practical requirements. It was we believe the protection offered by the British Patent Law, which, in the case of this very instrument, allowed Siemens to work it out in England, and so helped him eventually to find his home among us, and to give us primarily the benefit of his great inventiveness in all directions; while the want of similar protection under German law at that time rendered it practically impossible for him to work out so difficult an invention in his own country.

In electric invention William Siemens has been associated with his brother Werner, and the world has profited largely by this brotherly cooperation of genius. More than a quarter of a century ago, they brought out what is now known as the Siemens armature. The writer well remembers admiring it greatly when he first saw it (he believes at the London Exhibition of 1862), mounted between the poles of a multiple steel horseshoe magnet and serving for the transmitter in an electric telegraph. That was what we may now call the one-coil Siemens armature. It suggested inevitably the mounting of two or more coils on the same iron core, in meridional planes at equal angles round the axis, and as nearly equal and similar in all respects as is allowed by the exigencies of completing the circuits with the different portions of wire laid over one another, and bent to one side or the other, to avoid passing through the space occupied by the bearing shaft. The principle of electro-magnetic augmentation and maintenance of a current without the aid of steel or other permanent magnets, invented by Werner Siemens, and also independently by Wheatstone and S. A. Varley, was communicated to the Royal Society by William Siemens on February 14, 1867, in his celebrated paper "On the conversion of dynamical into electric force without the aid of permanent magnets." This paper is peculiarly interesting, as being the first scientific enunciation of that wonderful electro-magnetic principle, on which are founded the dynamo-electric machines of the present day. Soon after came the Paccinotti-Gramme ring, from which followed naturally the suggestion of the mode of connection between the coils of a multiple-coil Siemens armature, described in the Siemens-Alteneck patent of 1873, and made the foundation of the Siemens dynamo as we now have it, whether as given from the Siemens firm, or with the modifications of details and proportions, valuable for many practical purposes, which have been contributed by Edison and Hopkinson. The evolution of the Siemens armature, as we now have it, in this splendid machine, from the rudimentary type which the writer saw a quarter of a century ago, is one of the most beautiful products of inventive genius, and is more like to the growth of a flower than to almost anything else in the way of mechanism made by man.

---

[1] The Steel Engraving, which was put in hand some time ago while the life which has now passed away was rich in promise as well as achievement, nished. It will be issued with a future number.—ED.

Space prevents us from more than mentioning the works of William Siemens and his brothers, Werner and Carl, in land and sea telegraphic engineering, and their great achievements in Atlantic cable-laying. The *Faraday* bore particularly the impress of William Siemens's practical genius. It is remarkable that a ship capable of doing what no other ship afloat can do in the way of manœuvre, as has been proved by her success in the difficult and delicate operations of laying and lifting cables in depths of 2500 fathoms, and of cable repairing in all seasons and all weathers, should have been the work of a landsman, born in the middle of Europe, who early made himself a sailor in cable-laying expeditions in the Mediterranean and the Black Sea, but whose life has been chiefly devoted to land engineering and science.

On the 19th of this November the writer of the present article was accosted in a manner of which most persons occupied with science have not infrequent experience:—"Can you scientific people not save us from those black and yellow city fogs?" The instant answer was—"Sir William Siemens is going to do it; and I hope if we live a few years longer we shall have seen almost the last of them." How little we thought that we were that very evening to lose the valuable life from which we were promising ourselves such great benefits. May we not hope that, after all, the promise was not vain, and that, although Sir William Siemens is gone from among us, the great movement for smoke abatement, in which he has so earnestly laboured during the last three years of his life, may have full effect.

Just nine days previously, the writer had received a letter from Sir William Siemens, saying nothing of illness, but full of plans for the immediate future: chiefly an address to the Society of Arts, and the realisation at Sherwood of his method for the smokeless supply of heat to a steam boiler, by the combustion of hydrogen, carburetted hydrogen, and carbonic oxide, obtained from the conversion into these gases of the whole combustible material of the coal, together with some hydrogen and oxygen from water, and oxygen from air, in his gas-producing kiln. "The producer will be in full operation at Sherwood by that time" were almost the last words received by the writer from his friend, kindly inviting him to come and see the new method in operation at the end of the present month. A short time before, in travelling home from Vienna, where they had been associated in the British Commission for the Electrical Exhibition, Sir William Siemens had told the writer that without waiting for a perfected gas-engine to use the products of combustion as direct motive agent, and so give the very highest attainable economy, he expected by using the gas from his producer as fuel for the fire of a steam-boiler, even on a comparatively small scale, like that of his appliances at Sherwood for electric lighting and the electric transmission of power, to be able to obtain better economy of coal for motive power than by burning the coal directly in the usual manner in a furnace under the boiler. And further, what is specially interesting to persons planning isolated installations for electric light, he believed that the labour of tending the producer and boiler and steam-engine would be on the whole considerably less than that which is required on the ordinary plan, with its incessant stoking of coal into the furnace under the boiler, as long as steam is to be kept up. There is something inexpressibly sad, even in respect to a comparatively small matter like this, to see the active prosecution of an experiment so full of interest and so near to a practical solution, suddenly cut short by death. But the great things done by Siemens with gas produced in the manner referred to above, first in the gas glass furnace, described with glowing admiration by Faraday on Friday evening, June 20, 1862, in his last Royal Institution lecture, and more recently in connection with another great and exceedingly valuable invention, the Siemens process for making steel, by using the oxygen of iron ore to burn out part of the carbon from cast iron, and still more recently in the heating of the retorts for the production of ordinary lighting gas, by which a large increase has been obtained in the yield of gas per ton of coal used, are achieved results which li after the inventor has gone, and which, it is to be l will give encouragement to push farther and farther on i practical realisation of the benefits to the world from th legacy of his great inventions.

A most interesting article on the life and work of S William Siemens in the *Times* of November 21 conclud with the following words, in which we fully sympathise:—"Those who knew him may mourn the kindly heart, generous noble nature, so tolerant of imperfect ledge, so impatient only at charlatanism and dishonesty the nation at large has lost a faithful servant, chief amon those who live only to better the life of their fellow-me by subduing the forces of nature to their use. Lookin back along the line of England's scientific worthies, the are few who have served the people better than this h adopted son, few, if any, whose life's record will show long a list of useful labours."

In private life Sir William Siemens, with his lively bright intelligence always present and eager to give pleasure and benefit to those around him, was a most lovable man, singularly unselfish and full of kind thought and care for others. The writer of the present article has for nearly a quarter of a century had the happiness of personal friendship with him. The occasions of meeting him, more frequent of late years, and more and more frequent to the very end, are among the happiest of recollections. The thought that they can now live only in memory is too full of grief to find expression in words.

WILLIAM THOMSON

In addition to the above notice by a master-hand we give the following details of Sir William Siemens's life and of the sad and solemn closing scene.

CHARLES WILLIAM SIEMENS was born at Lenthe, in Hanover, on April 4, 1823; he was educated at Lübeck, the Polytechnic School of Magdeburg, and had the advantage of sitting for a couple of sessions under Professors Wöhler and Himly at the Univerity of Göttingen, finishing his academical career at the age of nineteen. He stayed one year at the engine works of Count Stolberg, and when twenty years of age landed in England to introduce a new process of electro deposition, and, as stated above, was so successful that he made England his home. Another early invention of the two brothers was one which Faraday lectured upon at the Royal Institution one Friday evening under the title of the "Anastatic Printing Process of the Brothers Siemens."

Between his twentieth and thirtieth years he was mainly engaged in problems connected with mechanical engineering, improving the chronometric governor, bringing out a double-cylinder air-pump and a simple water-meter which has been extensively used both in this country and on the Continent. When twenty-four years of age he constructed a four horse-power steam-engine, with regenerative condensers, in the factory of Mr. John Hicks, of Bolton, and the Society of Arts acknowledged the value of the principle by giving him their gold medal in 1850. At this time also he made a modification of Grove's secondary battery, to which he referred two years ago at the Jubilee Meeting of the British Association. When just over thirty years of age he received the Telford prize and premium of the Institution of Mechanical Engineers for his paper "On the Conversion of Heat into Mechanical Effect," in which he defined a perfect engine as one in which all the heat applied to the elastic medium was consumed in its expansion behind a working piston, leaving no portion to be thrown into a condenser or into the atmosphere, and advised that expansion should be carried to the utmost possible limit. In taking up the question of heat he adopted the dynamical theory as the result of a study of the works of Joule, Mayer, and others, and we find him when thirty-two years of age exhibiting two steam-engines with regenerative condensers, the one of twenty and the other of seven horse-power at the Paris Exhibition of 1855.

Between his thirtieth and fortieth years he read several papers before the Institution of Civil Engineers on electrical subjects, and before the Institution of Mechanical Engineers upon the various inventions which he had already brought out. During this period also was established the firm of Siemens Brothers, which has become so famous for their machines, and submarine and land lines, four Transatlantic cables, the Indo-European line, the North China cable, the Platino-Braziliera cable, and others. In 1860, when engaged in superintending the electrical examination of the Malta and Alexandria telegraph cable, he thought of using the increased resistance of metallic conductors due to rise of temperature as a means for measuring temperature, and brought out next year a pyrometer based upon this principle.

He was now also engaged with his brother, Mr. Frederick Siemens, upon that invention with which his name has since been mainly connected—the regenerative gas furnace. By means of this furnace, which is now used all over the world, two evils which formerly appertained to heat furnaces are cured, viz. the discharge of the products of combustion at a very high temperature and in an incompletely combined state. Another advantage of this furnace is the very high temperature that could be attained by its use, and from the very first its author looked upon it as capable of accomplishing what Reaumur, and after him Heath, had proposed, namely, to produce steel on the open hearth. It was in 1862 that Mr. Charles Atwood made the first attempt to produce steel in this manner at Tow Law under a license from Mr. Siemens; but, though partially successful, it was afterwards abandoned; after one or two other disappointments, Mr. Siemens had to take the matter into his own hands, and having matured the process at his experimental works at Birmingham, he laid the foundation of an industry which now employs thousands of workmen at the works of the Landore Company, Vickers and Co. of Sheffield, the Steel Company of Scotland, and others, about half a million tons of mild steel having been produced last year in Great Britain alone. This steel is now used almost exclusively in Her Majesty's dockyards in the construction of the boilers and hulls of ships, and its use in private yards is extending rapidly.

On February 14, 1867, he brought before the Royal Society the paper on the conversion of dynamical into electrical force referred to by Sir William Thomson.

Not only to these large applications of electricity did Sir William Siemens direct his attention but to electro-metallurgy and horticulture. Those who were present at his lecture to the Royal Institution on March 12, 1880, will remember the stream of light which poured forth from his electric furnace when the lid was taken off the crucible to pour the fused steel into the mould, and the result of his experiments on the influence of electric light upon plant growth in the exhibition of peas, roses, lilies, and strawberries at this early season with the fruit partially developed. But the space at our disposal will only allow us to remind our readers of others of his inventions, his bathometer for measuring the depth of the sea, and his attraction meter (*Phil. Trans.*, 1876); the selenium eye, which was sensitive to variation of colour; the regenerative gas burner, and regenerative gas and coke stove; the hypothesis of the conservation of solar energy; all of which have appeared from time to time in these columns. The last time Sir William Siemens lectured in public in this country was at the Institution of Civil Engineers on March 13 last, on "The Electrical Transmission and Storage of Power," the evening the attempt was made to blow up the offices of the Local Government Board by dynamite, when, although a portion of the glass was shattered in the theatre of the Institution, the lecturer resumed the thread of the discourse after a moment's pause as though nothing had occurred.

Sir William was a member of nearly all the scientific societies of Great Britain; he was the senior member of council of the Institution of Civil Engineers; he was elected a member of the Royal Society in 1862, and had twice served on the council of that body. He has been President of the Institution of Mechanical Engineers, twice of the Society of Telegraph Engineers, of the Iron and Steel Institute, and last year, at Southampton, of the British Association; whilst at the time of his death he was Chairman of the Council of the Society of Arts. He was made a D.C.L. of Oxford *honoris causâ* in 1870, an LL.D. of Glasgow in 1880, of Dublin in 1882, in which year the University of Würtzburg also bestowed on him its honorary Ph.D. He was elected with Sir Henry Bessemer, the first honorary members of the Gewerbe-Verein of Berlin, besides being a corresponding or ordinary member of several learned societies in Europe and America.

He received prize medals at the Exhibitions of 1851 and 1862, and a *Grand Prix* at the French Exhibition of 1867 for his regenerative gas furnace and steel processes. In 1874 he was presented with the "Royal Albert Medal," and in 1875 with the "Bessemer Medal" on account of his scientific researches and his inventions relating to heat and metallurgy, whilst only last week the Council of the Institution of Civil Engineers awarded him the Howard Quinquennial Prize for the advances he had made in the manufacture of iron and steel. He has received recognition of his services to pure and applied science from the Emperor of Brazil, the Shah of Persia, and from France both under the Empire and the Republic, whilst in March last Her Majesty was graciously pleased to confer upon him the honour of knighthood.

It was whilst returning from the monthly meeting of the Managers of the Royal Institution on November 5 that he met with the accident that accelerated his death, which took place on Monday, the 19th inst.

In accordance with the desire of the whole community, the public ceremonial performance of the last sad rites took place in Westminster Abbey on Monday last before the remains were conveyed to their resting-place in the cemetery at Kensal Green. The Prince of Wales placed his name at the head of the requisition submitted to the Dean of Westminster, asking that a public funeral might mark the recognition of Sir William Siemens's claims to be held in remembrance as a public benefactor, while few were more deeply affected at the graveside than the men who came to show their respect to a kindly master.

At the Abbey, according to the *Times* report, the distinguished public personages and representatives of scientific bodies assembled in the Jerusalem Chamber or in the Abbey, members of societies not attending in official capacities having places assigned them in the sacrarium or transepts, the choir and seats under the tower being reserved for presidents, vice-presidents, members of council, and officers of the societies invited to be present. The ancient tapestried chamber which has of late years been the scene of several such sad gatherings was filled—indeed, crowded—with the many warm friends and admirers of the deceased. His Royal Highness the Prince of Wales was represented by one of his grooms-in-waiting, Mr. Andrew Cockerell. The German Ambassador, Count Münster; the Chancellor of the Exchequer, Mr. Childers; the First Commissioner of Works, Mr. Shaw-Lefevre; Lord Bramwell, and Lord Claud Hamilton were also present; together with Mr. F. R. Pickersgill, Keeper of the Royal Academy, representing the President, Sir F. Leighton; Sir Douglas Forsyth, Sir Theodore Martin, Sir J. M'Garel Hogg, M.P., Sir Henry Tyler, M.P., Major-General Sir Andrew Clarke, General Crofton, Major-General Pasley; Mr. Fung Yee, secretary to the Chinese Legation, and others.

Taking the scientific Societies and their representatives in the order in which they were marshalled to join the procession, there were as pall-bearers—Prof. Huxley, President of the Royal Society; Sir Frederick Bramwell, predecessor of Sir William Siemens in the office of Chairman of Council of the Society of Arts; Mr. Brunlees, President of the Institution of Civil Engineers; Mr. Percy Westmacott, President of the Institution of Mechanical Engineers; Prof. Sir W. Thomson, for the British Association; Prof. Tyndall (Royal Institution); Mr. Willoughby Smith, President of the Society of Telegraph Engineers and Electricians (a society of which Sir William was the first president); and Sir James Ramsden (in the unavoidable absence of Mr. B. Samuelson, M.P.), representing the Iron and Steel Institute. The Royal Society was further represented by the treasurer, Dr. John Evans, and the secretaries, Prof. G. G. Stokes and Prof. Michael Foster; and among other well known members of this, the oldest of the learned and scientific societies, were Sir Joseph Hooker, Sir Frederick John Evans, K.C.B., Mr. Norman Lockyer, Mr. Warrington Smyth, Dr. Hopkinson, Prof. W. G. Adams, Prof. Bartholomew Price, Prof. Chandler Roberts, Prof. R. B. Clifton, Prof. Carey Foster, and Mr. R. W. Mylne. The Society of Arts was represented by the following Members of Council:—Sir Frederick Abel, C.B., F.R.S., Mr. A. Carpmael, Mr. Andrew Cassels, Lord Alfred S. Churchill, Sir Philip Cunliffe-Owen, Mr. B. F. Cobb, Mr. H. Doulton, Capt. Douglas Galton, C.B., F.R.S., Admiral Sir Edward Inglefield, C.B., F.R.S., Mr. T. V. Lister, Mr. Owen Roberts, Lord Sudeley, and by Mr. H. Trueman Wood, secretary, Mr. H. B. Wheatley, assistant secretary, Mr. Howard Room, and other officers. Of the Institution of Civil Engineers there were past presidents—Sir John Hawkshaw, F.R.S., Sir Charles Hutton Gregory, K.C.M.G., Mr. Hawksley, Mr. Bateman, Mr. Barlow, Mr. Abernethy; vice-presidents—Mr. Edward Woods, Mr. G. B. Bruce; Mr. Charles Manby, honorary secretary; Sir John Coode, Mr. Berkley, Dr. Pole, Mr. Hayter, Sir Robert

Rawlinson, C.B., Mr. E. A. Cowper, Mr. Rendel, Mr. B Baker, Sir James N. Douglass, and Mr. J. W. Barry, members of Council; and Mr. James Forrest, secretary, and Mr. H. E. Eaton, assistant secretary. The Institution of Mechanical Engineers sent—Mr. Ramsbottom, a past president, for long mechanical engineer to the London and North-Western Railway Company: Mr. Rennie and Mr. T. R. Crampton, vice-presidents; Mr. W. Anderson, Mr. Kitson, Mr. Peacock, Mr. Richardson, Mr. J. Tomlinson, jun., Mr. Tweddell, and Mr. Price Williams, members of Council; Mr. W. R. Browne, secretary, and Mr. A. Bache, assistant secretary. Prof. Bonney's name may be given as one of many connected with the British Association; and as members of the London Institution those of Mr. Warren De La Rue, F.R.S., Mr. W. Bowman, F.R.S., its honorary secretary; and Dr. Gladstone, F.R.S. From the Society of Telegraph Engineers there were—Mr. Latimer Clark, Lieut.-Col. Webber, R.E., C.B., past presidents; Mr. Spagnoletti, Prof. D. E. Hughes, F.R.S., and Sir Charles Bright, vice-presidents; Mr. Stroh and Mr. H. C. Forde, of the Council; and Mr. F. H. Webb, secretary. The Iron and Steel Institute, of which Sir W. Siemens was a past president, was also represented by Mr. W. Whitwell, Mr. G. J. Snelus, Mr. Edward Williams, Mr. T. E. Horton, Mr. Daniel Adamson, Mr. E. Windsor Richards, and Mr. J. S. Jeans (secretary). The Royal Astronomical Society had a fitting representative in the Astronomer Royal, Mr. W. H. M. Christie, a vice-president. Mr. Horace Jones, president, and Mr. Mac Vicar Anderson, honorary secretary, of the Royal Institution of British Architects, and Dr. W. H. Perkin, F.R.S., President of the Chemical Society, represented those bodies. For the Royal Meteorological Society, there were the President, Prof. J. K. Laughton; Mr. G. J. Symons, F.R.S., the honorary secretary; the Hon. Rollo Russell, Mr. R. J. Lecky, and Dr. J. H. Gilbert. From the Institute of Naval Architects there were two vice-presidents—Mr. N. Barnaby, C.B., Director of Naval Construction; Mr. James Wright, C.B., Engineer-in-Chief at the Admiralty; and Mr. George Holmes, secretary to the Institute. The Society of Engineers was represented by the President, Mr. Jabez Church, Mr. Nursey, of the Council, and Mr. Bartholomew Reed, secretary. There were also present representatives of the Geological Society, the Chemical Society, the Physical Society, and the Society of Chemical Industry. The German Athenæum in London was represented by a deputation, headed by Count Victor Gleichen, its honorary president, and including Mr. Alma Tadema, R.A., Mr. Carl Haag, Dr. Hess, Mr. F. Rosing, Mr. E. Meyerstein, honorary secretary, and Mr. C. Sevin.

Sir Henry Bessemer wrote to the secretary of the Iron and Steel Institute expressing his deep regret that an attack of bronchitis prevented him from being present.

Forming a long procession, the occupants of the Jerusalem Chamber filed past the Westminster Schoolroom, and, meeting the family mourners at the entrance from Dean's Yard, took their appointed places, and followed the coffin through the cloister to the Canons' door, in the south aisle of the Abbey. The coffin was covered with wreaths sent from nearly every country in Europe.

A great part of the large assemblage joined the procession formed after the Abbey service and accompanied the remains to Kensal Green. At the cemetery there were also present very many of the workmen from the telegraph works at Woolwich. A bank of grass and flowers breast high encircled the head of the grave, and the sides of the interior were hidden by fern-fronds and flowers.

The inscription on the coffin was simply—

C. William Siemens,
Died 19th Nov., 1883.
Aged 60 years.

THE FOREST LANDS OF FINLAND

Finland: its Forests and Forest Management. Compiled by J. C. Brown, LL.D. (London: Simpkin, Marshall, and Co., and William Rider and Son, 1883.)

AT a time when renewed effort is being made in our own country to stir up interest in the subject of forestry, it is instructive to notice what progress is being made in woodcraft in other lands. Sir Richard Temple brought before the Social Science Congress at its recent meeting the condition of our home and colonial forestry; next year an international forestry exhibition is to be held in Edinburgh; and Sir John Lubbock has given notice of a motion affecting forestry for next session in the House of Commons.

Dr. Brown divides his book into three parts, dealing respectively with the lakes and rivers of Finland, its forest economy, and its physical geography, including geology. The first part, though decidedly interesting, savours rather too much of the guide-book style, and is interspersed with adventures and scriptural quotations. Water occupies two-fifths of the area of Finland, which is called by its inhabitants "The Land of a Thousand Lakes," and most of the internal communications of the country are effected along its lakes and streams. Another poetical designation, "The Last-born Daughter of the Sea," refers to the recent upheaval of the Finnish area, a rising which is still in progress, as is proved by the continuous shallowing of the waters on the Baltic coast-line. The country abounds in interesting glacial phenomena, but we must confess to a feeling of disappointment with the geological as well as with the first portion of the work. Moreover, ordinary care has scarcely been exercised, otherwise we should not read of "palatal mansions," of boulders "marled or variagated" by lichens, of "moluscs," "mamifers," and "carnivori," nor yet of "the old Taurentian formation," to say nothing of the excessively vague notion conveyed by such an expression as "pre-Adamic times."

The second part, dealing with forest economy, occupies rather more than half the book, and constitutes presumably the *raison d'être* of the whole. Forest products form more than half the total value of exports from Finland, and it is estimated that 64 per cent. of the entire surface of the land is covered with forests, which up to quite recent times were subjected to the most reckless waste. Finland is the only country in Europe in which *sartage* that is, the practice of setting fire to the trees in order to clear the ground, is still carried on extensively. The clearing away of the woods is to prepare the ground for agriculture, but as much or more by the preparation of the soil as by obtaining space for the cultivation contemplated, and this is the peculiarity of the usage. The trees growing on the spot selected are burned, and the seed is sown on the soil thus manured with the ashes of the trees. The effects of *sartage* in other European countries, in India, and in North America, are brought under notice and discussed at some length. In France it is a practice recognised both in forest science and in forest management, but whereas it was formerly resorted to largely it is now adopted only in special circumstances. It is there found that the oak, particularly a hardy variety known as the *rouvre*, of all forest trees sustains best the treatment of *sartage*. In the Ardennes the coppice woods of *rouvre*, which are so treated, yield excellent firewood and charcoal. The burning is carried out in August and September, and, at the proper time for sowing cereals, rye or buckwheat is scattered over the ground and covered with a light hoe. After the crop is reaped the young tree-shoots begin to grow rapidly, but it is often necessary in order to insure perpetuity of good growths to plant out seedlings, and this is especially the case with the oak.

At the present time there are in Finland districts in which *sartage* is now prohibited, others in which it is carried on under restrictions, and others in which it is tolerated and apparently freely practised. Should the cleared ground not be retained permanently under agriculture, it is likely to become covered again with a crop of self-sown trees, of the same kind as those destroyed, or of a kind of higher pecuniary value. On the banks of the Saima See, for example, fir trees have been replaced either by firs or by birch. The fir or pine may be of more value for building purposes, but the birch supplies a better firewood, and for this there is and probably will long continue an ever-increasing demand in St. Petersburg, to which it can be sent from most places in Finland by water.

When a crop of trees after destruction is not replaced by another crop, the proximate effect upon the climate is generally considered to be beneficial to agriculture. But in Sweden in many districts in which the forests have been cleared away it is remarked that spring now begins a fortnight later than it did in the last century, and this is attributed to protracted frost due to diminished humidity of the atmosphere.

The improved forest economy of France dates from the issue of the celebrated Forest Ordinance of 1669, if not from a much earlier period. But in Finland all improvements in forest economy have been effected since 1809, and particularly during the last twenty-five years. Though formerly an independent country, Finland was for a long time a province of Sweden, and in 1809 it was annexed to the dominions of Russia as a Grand Duchy, with the enjoyment of pre-existing privileges and of government under its own laws issued in accordance with its Constitution. In 1848 were sent out Imperial Instructions relative to the management of the Crown forests, along with regulations respecting projected surveys, and in 1858 new arrangements for the management of these forests were made.

The forest administration of Finland is now in the hands of well-trained officers, and much of the lavish waste of former days has ceased. By giving more attention to considerate thinning, by more skilful conservation and more scientific exploitation, it was felt that the "produce and the products of the forests might be equalised approximately, if not perfectly," and one object aimed at in the inspection of forests is to prevent the removal of trees being effected more rapidly than the re-growth. As has been remarked, Finland has a constant market for firewood and timber in St. Petersburg, where firewood is now more expensive than coal brought from Britain.

It is to its School of Forestry at Evois that Finland looks for its supply of trained forest conservators. This school was opened in 1859, and intending students were required to produce before admission a university diploma, or a first class certificate of the completion of the course of study at a gymnasium. Closed after a time from lack of students, it was reorganised and reopened in 1874. The course of study occupies two years, and the subjects are forest science, surveying, engineering, rural economy, legal economy, and drawing. In July and August the pupils are required, for the sake of practice, to measure fields and woods, and to estimate the quantities of standing timber. We observe that under forest science is included "the science of hunting," whereat many an English youth would no doubt be inclined to say "Happy Finlanders!" Officered by men trained in this school, the Finnish forest administration is now in a position to attain objects identical with those of the advanced forest economy of Europe: first, to secure a sustained production from the forests; secondly, to secure along with this an amelioration of their condition; and thirdly, a reproduction of them by self-sown seed when felled.

Readers who are interested in forest conservancy will find much valuable information in the middle section of Dr. Brown's work. The subject is one which must ere long force itself on the attention of political economists. The reckless clearances that have been effected in our Canadian territories are approaching a limit; the most cautious estimates do not allow a longer period than fifteen years for the exhaustion of our Canadian timber lands at the present rate of consumption, and one very trustworthy and experienced authority limits it to seven years.

W. FREAM

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Optical Phenomena

THE phenomenon described as "Cloud-Glow" by your correspondent, Mr. F. A. R. Russell, in NATURE of the 15th inst. (p. 55), and by Mr. J. J. Walker in your last issue (p. 77), was observed here by me; as, however, the time my observation commenced (5 p.m.) was three-quarters of an hour later than the time given by Mr. Russell (4.18 p.m.) it is probable that many of the features described by him had faded before the phenomenon came under my notice. As seen by me, the appearance consisted of an arc-like mass of glowing vapour of a ruddy hue, but of a tint not familiar to me, in the western horizon, extending from the north-west to a point near the South Pole. The centre of the mass was about due west, and was there some 25° above the horizon. There was no wind; there were no cirri. The sky was clear and the air transparent, and I could not associate the appearance with anything like a "cloud-glow." It seemed to me like the blaze of a great conflagration seen through a smoky medium, and I expected every moment to see the fire-engines rush past me. At dark (6 p.m.) there were long pallid streaks of polar auroral light, proceeding from a centre in the north-west. These presented no signs of the flickering activity usually accompanying auroral manifestations. Soon after 7 p.m. all traces of polar aurora vanished. It may be mentioned that, while instances of aurora have been common here throughout the autumn, on one occasion only have flashing rays and beams been present.

Every sunset since the 9th, when the condition of the weather permitted—somewhat rarely—the remarkable glow under notice has been visible in the west, sometimes marked and prominent, as on the 17th inst., at others somewhat indistinct, according as the state of the atmosphere served.

Here to-day, after the storms of yesterday, blue sky prevailed, and the afternoon proved favourable for observation. The sky was clear; the air, washed by frequent rains, was transparent; wind south-west and tranquil; barometer low; thermometer at 2 p.m. 48°. At 4 p.m. a great arc like bank of dusky coloured vapour, extending as before from north-west to south, was discernible. On the sun declining behind the mass, it was suddenly shorn of its beams, and looked like the moon when rising. In a few minutes the vaporous bank assumed the peculiar vivid ruddy hue distinctive of the phenomenon; the blue colour of the sky changed to green. The green was speedily replaced by the ruddy tint before described, which presently suffused the whole hemisphere, tinged the entire landscape, and presented an appearance of which I have never seen the like. The colour was deeper round the horizon than at the zenith. The colour gradually faded as the vaporous glowing mass sank in the western horizon, and at 5.30 had left no trace.

Worcester, November 26 J. LL. BOZWARD

P.S.—The atmospheric effect described as cloud-glow was visible here to-night. There was a cloud canopy, but at 4.30 the ruddy light was visible under the canopy over the whole hemisphere. The ruddy light was manifest in a marked manner at sunrise on the 24th, and was discernible this morning. Probably the phenomenon is attributable to the aqueous vapour in suspension in the atmosphere. J. LL. BOZWARD

Worcester, November 27

THE remarkable cloud-glow after sunset on November 9 was seen by me at Sudbury on the southern border of Suffolk. I was struck by the softness and uniformity as well as brightness of the glow, and by its contrast with the pale greenish hue of the clear sky around, from which it was separated by a frame of nearer clouds in shade. When I first noticed it the (upper) margin was about 15° above the horizon (estimated from memory). Presently the glow diminished in brightness and increased in extent upward to about 40° above the horizon; and at the highest (nearest) part the delicate structure of the cirrus was visible.

Was it noticed at any place further north than Sudbury?

Woodbridge, November 25 HUBERT AIRY

IN travelling up from Leeds on Monday afternoon I was able to watch the whole progress of the remarkable sunset sky on that afternoon. The sun went down quite clear, and the sky was all but cloudless. Shortly after sunset a crimson arch appeared stretching from south-east to north-east, with a very clear greenish blue sky beneath it in the east. This crimson arch gradually proceeded westwards over the sky, and at about 4.20 was stretching from south-west to north-west. At this time it developed a number of well-defined, pointed rays or streamers radiating from the point where the sun was below the horizon. Between the arch and the western horizon was a sky of a bright silver-white colour, which was so brilliant that it gave us quite a second daylight. The crimson arch continued to sink towards the western horizon, the streamers still retaining the same relative positions. At about 4.40 it formed simply a bright crimson band along the western horizon, and the streamers still pointing out from it gave the appearance of some large forest on fire in the west. Finally, at 4.50, when we were some twelve miles north-west of Nottingham the crimson arch had entirely vanished below the horizon. At one time, when the arch was at its brightest, with the silver-white sky beneath it, it had exactly the appearance of the aurora, except that the streamers remained fixed in relative position. In the silver-white sky there seemed to be a very thin cloud layer. A. TARN

31, Mornington Road, N.W., November 27

OPTICAL phenomena of a peculiar nature appeared here on the 25th and 26th inst. On the 25th, shortly before sunset, the atmosphere, which was exceedingly clear except in the west, was suffused with a brilliant tint of lake. Over and to the left of the sun, which appeared to shine with a remarkably white light, there was a heavy cumulus, the edges of which were tinted with a strange, olive-green colour. After sunset the sky in the east became gradually of a more brilliant rose tint, which continued a long time after the sun's rays ceased to be reflected from a long, curled streak of cirro-filum, at an altitude of 2600 feet. The sky nearer the zenith at 5 p.m. appeared to be of a sea-green tint. A little later, the most brilliant rose-coloured glow covered the western and south-western sky, which continued up to about 5.45 p.m., and might easily have been mistaken for a red aurora.

On the 26th a similar phenomenon took place upon a grander and more unusual scale. At 3 p.m., when the sky was totally devoid of higher cloud, the sun, which was shining with a remarkably white light like the electric light, was surrounded by a very broad halo of a uniform *pale pink* colour, whose exterior margin was very ill-defined. This halo was of about 22° radius and was totally devoid of the usual prismatic tints. A little before sunset the sky, which was clear except in the distant south-west, where there was a thin bank of cirriform cloud, became of a bright salmon colour. At 4.35 there was a beautiful display of *rayons du crépuscule* in the east-north-east, there being six larger and some smaller lake-coloured belts. But the most splendid phenomenon was yet to come. From 5.5 to 5.15 p.m. a brilliant arc of red light having the position of the sun for its centre, and having an altitude of about 25°, illuminated the western heavens. This light was bright enough to cast a vivid red glare on all objects seen in the opposite direction. From this arc throughout the whole of its extent arose bright rays of red light, divergent from the sun's position, the perpendicular one in the centre extending nearest to the zenith. The arc gradually sank towards the horizon, following the sun's westward declining course.

The barometer at the time was very low, the temperature high, and there was marked "visibility." To-night (27th) there is again a red glow, seen feebly through a thick sheet of cirriform cloud.

Is it possible that particles of ice-dust carried upwards to a great altitude in the extensive cyclonic disturbances now prevalent may have produced these phenomena? In any case it seems clear that the reflecting matter was in the first case very equally diffused, having no tendency to arrange itself in strips or cloudlets; in the second place of considerable vertical thickness; and thirdly, that its greatest altitude was upwards of thirteen English miles.

I hope that some of the readers of NATURE who have witnessed these phenomena may be able to explain them, and not least of all the pink halo. ANNIE LEY

Ashby Parva, Leicestershire, November 27]

IN connection with different singular atmospheric phenomena noticed lately in India, Ceylon, and even in our own country, I think an extract from a letter received by the last Cape mail may prove of interest to some of your readers. I may premise that my correspondent resides upon an open Karoo plain, where the atmosphere is always clear; such a "phenomenon" as a *fog* being unknown, and where the sunsets generally are of a beauty that I have not seen surpassed even in the tropics, a beauty, however, very evanescent, for it will be remembered that in those latitudes there is little or no twilight.

The letter is from about thirty-five miles south of Graaff Reinet, and is dated October 21. "Many of us out here are much interested in a very peculiar light visible in the west nearly every evening about an hour after sunset. It lasts until quite dusk, and throws a sort of lurid glare over everything, and the sky is angrily red; I have not seen anything about it in the papers, but the people were very full of it in Graaff Reinet. It is now about a month since we first noticed it."

M. Carey-Hobson

Pons' Comet and Meteors.—The Quadrantids

I see in Greg's list of possible cometary radiant points there is one given for Pons' Comet, the date December 6, radiant point R.A. 200°, N.D. 68°·5. The radius-vector of the comet at its descending node is 0·77, so that the likelihood of a shower of meteors seems very small; but it might be worth while to look out for one on the 6th of next month.

Pons' comet was just visible to my naked eye on the evening of the 19th—visible only by rare glimpses. On the 20th it was easily visible with the naked eye, almost steadily, so that it would be about of the 7th magnitude. Its tail is still very faint with a 4¼-inch refractor, and grows very slowly.

I would call the attention of observers of meteors to the favourable circumstances attending the next shower of quadrantids, as regards absence of moonlight and the convenient time at which the maximum will be reached. On the other hand, the radiant point will be low at that time, thus diminishing the number of meteors visible. I have examined my observations of this shower in 1859, and from 1872 to 1883, and find that the maximum takes place when the sun's longitude is nearly 282°. This will correspond at the next apparition to the middle of the night of January 2. The duration of the activity of this shower is short compared with that of some other periodical showers, and I am making a more minute calculation of it, the result of which I purpose sending to the *Astronomical Register*.

Sunderland, November 27 Thos. Wm. Backhouse

Meteor

A remarkable meteor appeared in the eastern sky this evening at about 8.30. Coming out of *Cetus* it travelled slowly towards *Orion*, being visible for five or six seconds. The head was rounded in front, about one-eighth of a degree wide, tapering backwards to the length of half a degree, distinctly bluish in colour, and leaving an indistinct trail of about twice its own length behind it. It was so bright and seemed so near that I took it at first for a firework of some kind. But it was undoubtedly a meteor. It died out silently, and without breaking up, at about 15° from the horizon. Birstal Hill, Leicester, November 20

Some Habits of Bees and Humble-bees

Have any of your readers noticed, or can any account for, a curious practice which I observed on several fine days this autumn among the humble-bees that frequented a bed of blue salvia, viz. that in piercing the calyx and upper end of the tube within it, they would invariably attack it on its *right-hand side*, *i.e.* the right side of the flower as it looks straight out from the stem. After having several times counted fifty or sixty such attacks in succession, I gathered a number of flowers at random and, carrying them indoors, requested my brother to lay each on its side, so as to show the hole uppermost; twenty-five out of twenty-six were without hesitation placed with the *right* side exposed, the remaining one was considered doubtful. The apparent rule of proceeding was this:—The bee alights on the under midrib or keel of the calyx, with her head towards the stem, then turning her head and fore feet slightly round to the right, inserts her proboscis just clear of the rib, the process being visible only to a person standing on that side of the flower. Whether the flower was on the north or south side of the bed, in shade or sunshine, made no difference, nor did it matter in which direction the bee was making her circuit round the bed. Where two flowers hung so close together as to touch, after piercing the right-hand one on its outer side, and satisfying herself that she could not conveniently push her way in between the two, she would fly off to another, losing the honey rather than attempt to reach it through the left side of the flower. This occurred repeatedly.

Is there anything in the structure of the calyx or in the position of the nectar that can explain this? Or is there a right and left-handedness in some families of humble-bees? Or can it be that a habit, perhaps accidentally established, may be rigidly pursued for a time, at the risk of occasional small losses, to be afterwards abandoned when the impulse is worn out, or when the results are found to be not worth the trouble of forming the habit? That small gains are sometimes neglected in obedience to a habit of quite recent formation, I had an instance a few summers ago, when watching a number of hive bees on a plant of common fuchsia. The greater part of its flowers had been pierced in the upper tube (probably by humble-bees), and my attention was drawn by the regularity and exactness with which the bees were flying straight to the tube, contrary to their usual practice of entering from below. But the flowers were not *all* pierced; and this was the curious part: when a bee had run round the tube and ascertained that there was no hole, she would give it up at once and fly to another, as though the pressure of the new habit would not permit any occasional recurrence to the good old-fashioned plan of entrance from below. Can blind obedience to an *order* given out by a superior have any place in apiary economy?

In this instance it was clear that the habit was fully formed, as regarded that particular plant: I tried to witness its commencement on another, and accordingly pierced as many flowers as I could reach on a fuchsia growing at some distance from the first. A few bees discovered my holes and made use of them, after which they showed considerable hesitation and confusion in their mode of attack, losing much time in hovering up and down as though thrown out of their usual routine; while on unpierced neighbouring plants the customary precision of aim at the lower opening of the corolla prevailed without interruption.

Reverting to the humble-bees on the blue salvias. That their piercing the flower *at all* is an occasional and not universal practice I am inclined to believe, from the totally different behaviour of a set *of apparently the same species* (though of this I cannot be certain) on the same plants during the early part of last autumn. Alighting on the lower lobe of the corolla and advancing inwards, the bee's weight forced open the throat of the flower, into which she then easily inserted her head. This plan was pursued with as much regularity as the opposite one was this autumn. On the same days it was amusing to observe the many fruitless attempts of hive bees to effect an entrance in the same manner. Their bodies being too light to weigh down the floor of the corolla, they would try in vain to force their heads in and always had to fly away disappointed, except when one more fortunate than the rest discovered a flower that had dropped from its calyx, when she would eagerly insert her proboscis into the open end of the tube.

Seeing their great anxiety to obtain salvia honey, I eventually expected to find them taking advantage, this year, of the holes ready made for them by the humble-bees, but strange to say they appeared to have quite deserted the plants, though swarming on a neighbouring bed of yellow Tagetes, an occasional wanderer only passing amongst the blue flowers, and without alighting.

Collingwood, Hawkhurst, November 21

Rudolphi's Rorqual

In a communication made to the Zoological Society on the 20th inst., when describing a specimen of Rudolphi's Rorqual (*Balænoptera borealis*), lately captured in the River Crouch, Essex, I said that this was the first well authenticated example of this species taken in British waters. My friend, Mr. J. E. Harting, has kindly called my attention to a paper which had for the time escaped my memory, published by Prof. Turner in the *Journal of Anatomy and Physiology* for April, 1882, in which a specimen is described which was captured near Bo'ness in the Firth of Forth in September, 1872, and of which the skeleton is now preserved in the Anatomical Museum of the University of Edinburgh. November 22

Reflection of Light

As showing how far under favourable conditions the reflection of light from a cloudy sky is visible, I may perhaps be allowed to mention that last night at nine o'clock the reflection of the London lights was remarkably strong. The sky was uniformly covered by a dense canopy of moderately high cloud, and the air very moist (humidity 95). Under such circumstances I have frequently seen at the same time the reflection of the London Brighton, Eastbourne, Hastings, and Tunbridge Wells lights, but last night this reflection in the case of London was peculiarly strong. In former years the light was of a reddish yellow, as is still the case with the lights of the other places named. But in the case of London, and less but perceptibly so in that of Brighton, the light has become of a more silvery hue, due doubtless to the extensive use of the electric light. The distance between this place (lat. 51°, long. 0) and London is about thirty-five miles in a direct line, and there is no place of any size between these points, so there can be no mistake about it; and that the reflection of light at such a distance should be visible seems worthy of notice. It would be interesting to know how far, under favourable atmospheric conditions, the reflection of the London lights can really be seen. W. J. TRENTLER

Fletching, Sussex, November 22

A Lunar Rainbow

ANY of your readers who happened to observe the heavens on Saturday night, the 17th inst., at about 11.15 to 11.30, could not fail to notice the beautiful lunar rainbow which was then visible. Though the moon had slightly passed its perigee, it was shining with such dazzling brilliance that the marbled shadows on its surface were almost effaced, and it hung in the heavens like a spotless crystal sun. The very stars seemed farther away, as though they had shrunk back, ashamed and frighted by the silver glory. Jupiter and Sirius alone stood fearless and undaunted—the former, below her to the left, as if in attendance, the latter far away in the starless south. A few featherlike clouds which the moon illumined with a splendour of her own, now and again sailed in stately silence across her path. but that portion which spread directly over her face, seemed to melt and become invisible like a snow flake on a warm hand, so that the cloud floated around her as a veil, fringing but not covering her face. It was when surrounded by one of these clouds that the rainbow became visible. I had never seen one before, so cannot say whether it was more distinct and bright than is usually the case, but I could see most vividly the red, yellow, green, and violet bands with their intermediate shades. The bow seemed formed on the cloud that shaded the moon at the time, and lay round her in a perfect, though comparatively small circle. It remained so for some nine or ten minutes, and then faded gradually away into a luminous halo of golden brown. Those of your readers who were fortunate enough to behold this beautiful phenomenon will, I am sure, agree with me that it was a sight not to be forgotten. J. C. KERNAHAN

The London Institution, November 24

Sudden Stoppage of Clocks

I HAVE four clocks in my house; one is on a wall that bears north-east and south-west, while the other three ranged nearly at right angles about north-west and south-east. The times of these clocks were not exactly together, there being from five to fifteen minutes between the times; but all of them stopped on the morning of November 18 at times as recorded by each between 3.25 a.m. and 3.40 a.m. Have any other clocks stopped on the same night? This place—Lurgybrack, Letterkenny, Co. Donegal, is in lat. 54° 56″ and W. long. 7° 41′ 52″.

Letterkenny, November 19 G. HENRY KINAHAN

Fog Bows

ON November 14, when driving about half way between Convoy and Letterkenny, Co. Donegal, I observed a very complete bow at about 1 p.m., due solely to a fog. For the most part it was quite white, but at the springing there were slight traces of prismatic colours. On November 15 at 7 a.m. at Letterkenny there was also a fog bow; this, however, had all through well developed prismatic colours. The 15th afterwards came on a heavy wet day; the 16th was fine; but since then there have been severe winds accompanied with sleet, snow, and rain. G. H. KINAHAN

Letterkenny, November 19

THE EARLY HISTORY OF THE HERRING[1]

THE Admiralty having intimated on July 31 that they were prepared to grant the use of a gunboat to enable the Board to undertake some investigations into the early history of the herring, the convener of the Committee appointed to carry on these inquiries made as complete arrangements as was possible in the limited time, and, along with Sir James R. Gibson-Maitland, proceeded to join Her Majesty's gunboat *Jackal* at Invergordon on August 6. Besides making preparations to collect material to illustrate the growth of the herring during the early stages of its development, it was thought desirable to make arrangements for the examination of the spawning grounds, in order to ascertain under what conditions the spawn was deposited. To assist in the work Mr. J. Gibson, D.Sc., of the Edinburgh University Chemical Laboratory, and Mr. J. T. Cunningham, B.A., of the Zoological Laboratory, were invited to join the expedition.

The trawls, dredges, and other appliances were taken on board on August 6, and on the following day the *Jackal* left Invergordon for the Moray Firth, and began the work of investigating the inshore spawning grounds lying between Wick and Fraserburgh. Each place examined was indicated by a number on the chart, and will be spoken of in the Report as a "station." During the month the *Jackal* was at our disposal sixty stations were made, and nearly as many by the *Vigilant* from the time she relieved the *Jackal* to her return to Granton on October 6. The plan generally adopted at the various stations consisted in (1) taking the depth and the surface and bottom temperatures; (2) collecting samples of water from the bottom, and of the mud, sand, &c., brought up by the sounding apparatus; (3) noting the nature of the surface fauna taken in the tow-net; and (4) examining and, when necessary, preserving the animal and vegetable forms brought up by the trawl, dredges, and tangles. In this way there has been collected a considerable amount of raw material, from which important results will in due time be obtained.

Not the least interesting part of the work consisted in experimenting with herring ova which were successfully artificially impregnated and developed. At first experiments were made with spawn obtained at Helmsdale on August 7, from herring which had been several hours out of the water; but the results being unsatisfactory, it was determined to obtain, if possible, the roe and milt from living fish. We, therefore, frequently remained during the night on the fishing ground, and boarded the herring boats when the nets were being hauled. The fishermen, always pleased to see us, rendered every assistance in their power. Selecting ripe fish, we expressed the roe and milt on squares of glass, which were then placed in carrying boxes specially designed for the purpose. The boxes were conveyed by the *Jackal* to a small laboratory near Geanies, which had been kindly placed at the disposal of the Committee. Once at the laboratory, the glass plates, with the developing eggs firmly adhering to them, were transferred to hatching boxes, through which a constant current of water flowed from a large tank. In from three to five days well-formed active embryos were visible through the thin transparent egg membrane, and in ten days we successfully hatched fry from the artificially impregnated ova. We soon discovered that success depended on having an abundant supply of pure sea-water at an equable temperature. Unfortunately, just as our arrangements for experimenting on a large scale were completed, the herring fishing in the Moray Firth came suddenly to an end, and it was impossible to obtain further supplies of eggs.

We next directed our attention to the nature of the surface forms, which are believed to supply the principal food for the herring fry, and when this, on account of the weather, was no longer possible, we proceeded to examine the mussel scalps in the Dornoch, Cromarty, and Inverness Firths.

As a full account of the autumn's work will be presented to the Board in time for the Annual Report, only a short statement is now given, indicating rather the lines of further investigations than the results already obtained.

---

[1] Preliminary Report of the Investigation Committee of the Fishery Board for Scotland.

During our stay in the Moray Firth our attention was constantly directed to the change in the position of the spawning grounds. It was stated that, some fifteen years ago, immense shoals of herring visited the inshore ground, in order to deposit their spawn in comparatively shallow water, but that now they had deserted their former favourite haunts for banks from thirty to eighty miles at sea, lying at a depth of from thirty to fifty fathoms. This has caused great distress, as from the absence of suitable harbour accommodation, the large boats fish from distant stations, and the inshore "takes" of the smaller boats (all of which can be beached) is not now sufficient to give employment to the local population in curing. The Report of the Commissioners for British Fisheries for 1862 gives the total take at the ports especially devoted to the inshore fishing, viz. Lybster, Helmsdale, Cromarty, Findhorn, and Buckie, as 158,314 barrels, whereas in 1882 it was only 31,574. On the other hand, at Fraserburgh, a great centre for the deep-sea fishing, the take has increased from 77,124 in 1862 to 233,297 in 1882. Though these figures, and our experience during the autumn, show conclusively that herring are no longer so abundant on the inshore grounds, they do not prove that the shoals are every year spawning farther and farther from our shores, as is often alleged, or that, if we continue to disturb the offshore spawning grounds as we have the inshore, they will disappear from our waters altogether. Some who have had considerable experience believe that spawn deposited in forty fathoms water never develops, and that even if it did the herring fry would perish for want of the proper nourishment.

The disappearance of herring from inshore grounds is accounted for in many ways by the fishermen. Some believe that the offshore fishermen prevent the shoals from reaching the coast by the many miles of nets which they throw across their path; others that the inshore fishing has been destroyed by the winter sprat fishing, most of the so-called sprats being young herring. The former explanation seems to imply that the inshore and deep-sea herring are identical, whereas the latter seems to indicate that they are different. The Report of the German Commission bears that there is a difference between the autumn and spring herring of the Baltic; there may also be a difference between the deep-sea and inshore forms. When this problem is solved we may be able to account for the disappearance of the inshore herring. Should some herring have been so modified that they prefer to spawn on rocky ground in shallow brackish water rather than on deep gravel banks in the open sea, or if herring return to their birthplace to spawn, it will be possible by skilful management to restore the inshore fishing to its original productiveness.

Having examined the inshore spawning grounds, we next proceeded to investigate the banks where the deep-sea herring were believed to spawn. At the outset we felt there was no evidence that these banks had not always been used by herrings as spawning beds. We do know, however, that as the herring boats increased in size enterprising fishermen were enabled to proceed farther to sea, and as a reward they discovered great shoals of herring, the comparative density and condition of which form an interesting subject for immediate investigation. It may have been a mere coincidence that this took place about the same time as the inshore shoals began to diminish. We have no reason for supposing that what we now speak of as deep-sea herring have not been as abundant for centuries as they are at the present day. Man, it seems to your Committee, is not likely much to reduce the number of herring some fifty miles at sea, however much influence he may exert over those which frequent our territorial waters. The time at our disposal did not permit our making a thorough examination of the offshore grounds; in fact, we were only able to begin this part of the work. But there can be no doubt, from the observations already made, that spawn is deposited on these banks, and that the slight difference of the bottom temperature (some 3° C.) would only slightly retard development. Further, the fry once hatched would find an ample supply of food in the rich surface fauna.

The Committee feel that, in order to obtain satisfactory information as to the food of the herring, it will be necessary to make continuous observations for a year or more at all the principal fishing stations around our coast. This could easily be undertaken through the fishery officers.

As to the so-called migrations of the herring, the Committee has not had sufficient time to make a careful investigation, but from the observations made it seems evident that, as the spawning season approaches, the isolated herring and the small groups congregate together, and thus form dense shoals. The shoals once formed instinctively select banks free from mud and shifting sand, and provided with numerous rocks and stones, or with an abundant coating of seaweeds. Having found a convenient bank covered with water at a suitable temperature, and with the requisite specific gravity, they hover over it, if left undisturbed, apparently not paying much heed to the claims of hunger, but feeding on whatever crustacea, sand eels, or other small forms come in their way. The spawn once ripe, they congregate at the bottom, the females depositing the roe on the rocks and seaweeds, to which it at once firmly adheres, and the males fertilising it with their milt. How long a period is required for the whole of the roe to escape has yet to be ascertained. Soon after the "shotten" condition is reached, both males and females begin to leave the spawning ground,—hunger being probably the chief factor in the dispersal of the spent fish,—and this goes on until the whole shoal is dispersed, the hungry disbanded members, either singly or in small companies, hurrying hither and thither in anxious search of food. When they have partly recovered from their exhausted condition they may collect into larger groups; but their further movements are probably largely influenced by the shoals of crustacea on which they chiefly subsist. In all probability their principal feeding ground lies somewhere between the Shetland Islands and the Scandinavian coast. This region is probably the great reserve feeding ground for the fish of the North Sea, and it should at an early date be carefully explored.

The examination of the three firths—Dornoch, Cromarty, and Inverness—has shown that they are all extremely well adapted for producing mussels. Part of the Dornoch Firth already is a considerable source of wealth to the authorities of Tain, but even there the cultivation might be greatly extended. The demand for mussels is great, and the want of them, when herring are unattainable, is often a great hardship to the fishermen; with a little care, the three firths mentioned would supply bait for the whole east coast of Scotland.

The Committee recommend the Board to remit the consideration of the Scottish mussel and oyster banks to a special committee, with the view of taking steps to have their complete control transferred from the Board of Trade to the Scottish Fishery Board.

As the work of the Committee proceeded they have been impressed with the fact that almost everything has still to be learned regarding the habits and life-history of all our food fishes, and they concur in the truth of the following extract from a recent report of the International Fisheries Exhibition:—"It is a very striking fact that the one point on which all speakers at the conferences held during the past summer at the Exhibition were agreed was this—that our knowledge of the habits, time and place of spawning, food peculiarities of the young, migrations, &c., of the fish which form the basis of British fisheries is lamentably deficient, and that without further knowledge any legislation or attempts to improve our fisheries by better modes of fishing, or by protection or culture, must be dangerous, and, indeed, unreasonable."

Further, your Committee feel that in order to make any progress the work must be undertaken in a systematic manner; the investigations must not be carried on by fits and starts, but continuously from month to month and from year to year, until all the facts have been collected and all the experiments made that are likely to throw any light on the difficult problems.

It having been alleged that the food fishes were disappearing from the eastern coasts of the United States, the Central Government in 1871 appointed a commissioner of fish and fisheries to inquire into the matter. The commissioner, instead of contenting himself with collecting evidence from people who knew little or nothing about the subject, proceeded to make careful and elaborate investigations. As the result of these inquiries the United States fisheries have been greatly improved, to the benefit of both the general public and the fishermen, and our knowledge of fish has been materially increased.

In the same way, and about the same time, a German Commission set to work, and although their results are not so striking, they are extremely interesting, a fourth section of their report, only published the other day, containing a careful description, with an outline drawing, of all the fish found in the Baltic.

The example set by America, Germany, and other Continental States we must follow. We have as a nation at last made a liberal acknowledgment of our ignorance, and at the conferences of the International Fisheries Exhibition expressed regret.

It is satisfactory that, while we are taking steps to increase our knowledge, we shall at one and the same time be improving our inshore fisheries. The measures necessary, *e.g.* for enabling us to discover for the first time when herring fry become maties, and when maties reach the stage of full herrings, are exactly the measures required for the artificial cultivation of the herring. From experience gained during the autumn we are now able to hatch immense numbers of herring; each herring produces from 30,000 to 50,000 eggs, but so small are they that 20,000 one layer thick can be placed on a square foot of glass, and from 1000 herrings it would be possible to obtain about 30,000,000 fry, and this in from ten to fifteen days. It is well known that where there is an abundance of herring there is also an abundance of cod and other food fish, hence the annual introduction of some millions of young herring into our territorial waters might serve to attract numerous large food fishes to our shores. And what is true of the herring holds for many other useful fishes, and some of them, such as the sole and turbot, which are less migratory than the herring, might be manipulated in much the same way as trout and salmon, if we only knew more of their habits.

In order to be able to carry on the work of investigation, the importance of which is now universally recognised, the Committee recommend that an application be made for sufficient funds to enable the Board to establish a marine station, and further that a steam vessel take the place of the *Vigilant* at present at the service of the Board.

The *Vigilant* is in every respect inadequate for the ordinary work of the Board, and if there is added to that work the acquiring of new knowledge as to the habits of our food fishes, the nature of their food, their time and place of spawning, and the way in which these may be influenced by the various modes of fishing, a steam vessel will be absolutely necessary.

The Committee have much pleasure in stating that they are deeply indebted to Lieut. Prickett, in command of H.M.S. *Jackal*, for the ready assistance rendered by him and his officers, and for their unfailing courtesy and kindness during the expedition.

They have also to state that it was a source of great satisfaction to them to find that the commander of the *Vigilant* was not only greatly interested in the work of the Committee, but that, having a strong instinct for scientific work, he will be able to render much assistance in any further investigations that may be undertaken.

To Mr. Romanes, F.R.S., the Committee are greatly indebted for many valuable suggestions, and they are also indebted for the use of the Marine Laboratory instituted some years ago by Mr. Romanes and Prof. Ewart. Without this laboratory much of the work which will form the substance of the forthcoming Report could not have been undertaken.

Edinburgh, November 5

THE ORIGIN OF CORAL-REEFS

SO much additional information has in recent years been obtained regarding the physical and biological conditions of the sea that such a problem as that presented by the coral-islands of mid-ocean may well be reconsidered. Several able naturalists have lately called attention to this problem, and have insisted that the generally received solution of it is not satisfactory. Among geologists there may not unreasonably be a good deal of unwillingness to admit that this contention can be well-founded. They have long been accustomed to regard Darwin's theory of coral-formation with justifiable pride as a masterpiece of exhaustive observation and brilliant generalisation. It has played an important part in their speculations regarding the larger movements of the earth's crust, and they have been so deeply impressed with its simplicity, and the grandeur of the conclusions to which it leads, that they will naturally and rightly refuse to surrender any portion of it save under the strongest compulsion of evidence. Some, indeed, may be inclined even to resent, almost with the warmth inspired by a personal injury, any attempt to show that it can no longer claim the general applicability which has been regarded as one of the strongest arguments in its favour. But the example of Darwin's own candour and overmastering love of truth remains to assure us that no one would have welcomed fresh discoveries more heartily than he, even should they lead to the setting aside of some of his own work. I propose to give here somewhat in detail the more important data accumulated in recent years on this subject, and to state the conclusions to which a careful consideration of the evidence seems to me inevitably to lead.

Before the memorable voyage of the *Beagle*, the generally received opinion regarding the origin of the circular coral-reefs or atolls of mid-ocean was that they had grown up on the rims of submerged volcanic craters. The enormous size of some of the atolls—thirty miles in diameter—might have been thought a sufficiently formidable objection to this explanation. But it did not appear insuperable even to so cautious a philosopher as Lyell, who only noticed it to refer his readers to the great dimensions reached by truncated volcanic cones, which he thought might retain their forms more easily under a deep sea than on land.[1]

An earlier and better theory, as Darwin admitted, had been started by Chamisso, who supposed that the circular form of an atoll was due to the fact that, as the more massive kinds of coral thrive most vigorously in the play of the surf, they naturally keep to the outside of the reef, and raise that portion to the surface first. But when Darwin's own views were published, first in abstract before the Geological Society in 1837, and subsequently more fully in his separate volume on the Structure and Distribution of Coral-reefs in 1842, they were soon generally accepted, and were regarded not only as affording a satisfactory explanation of the whole phenomena, but as comprising one of the most impressive generalisations with which geology, fertile in such achievements, had yet astonished the world.

---

[1] "Principles of Geology," 4th edit. (1835), vol. iii. p. 310.

The theory proposed by Darwin, now so familiar, connected all the types of reef together as stages of one long process, every step in which could be illustrated by actual examples. At the one end stood the fringing-reefs, some of which might only lately have been started upon a recently upraised sea-bottom. Out of this stage, by continuous or intermittent subsidence, came barrier-reefs. Then as depression went on and the islands encircled by the barrier-reefs disappeared, their sites were taken by atolls. Lastly, where the rate of subsidence was too rapid for the upward growth of the corals, an atoll might become a submerged bank. Not only was this explanation self-consistent, but it harmonised well with the conclusion, derived from totally different evidence, that there may have been widespread and long-continued subsidence over the ocean basins. It was moreover supported by the independent testimony of competent observers, who, with at least equal opportunities of studying the subject, had espoused Darwin's views. Of these witnesses the most important was undoubtedly Prof. Dana, who accompanied the Wilkes Exploring Expedition of 1838-42.[1] Another powerful ally was found in Mr. Couthouy, who had studied coral-growth in the Pacific and in the West Indian seas.[2] But even without the concurrent testimony of eye-witnesses the theory proposed by Darwin fitted so admirably into the geological theory of the day that it came itself to be used as one of the most cogent proofs of vast oceanic depression. And such is still the position which it holds.

By a gradually widening circle of observation, however, a series of facts has been established, which were either not known or only partially known to Darwin. It should be borne in mind that, compared with more recent explorers, he did not enjoy a large opportunity of investigating coral-reefs. So far as can be judged from his published works, he appears to have examined only one atoll—the Keeling reef; and one barrier reef—that of Tahiti. The Admiralty charts, the work of previous voyagers, and unpublished information communicated to him, enabled him to extend his generalisation over the whole of the rest of the coral-regions which he had not personally explored. The deep-sea expeditions of recent years have now brought so much new light to bear on the whole question that we are in a much better position to discuss it than he was, nearly half a century ago. Of a few of the more important investigations a brief *résumé* may here be given, and their bearing upon Darwin's theory of coral-reefs will then be discussed.

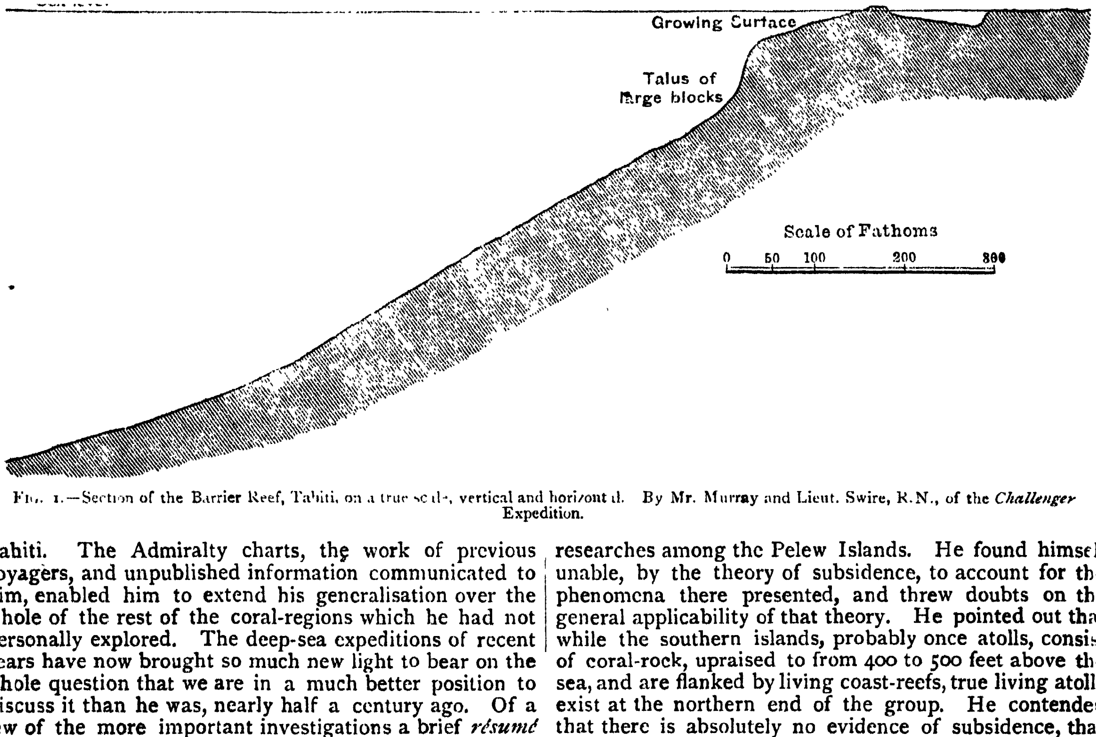

Fig. 1.—Section of the Barrier Reef, Tahiti, on a true scale, vertical and horizontal. By Mr. Murray and Lieut. Swire, R.N., of the *Challenger* Expedition.

As far back as the year 1851 the late L. Agassiz stated that, in his opinion, the theory of subsidence could not be applied in explanation of the Florida reefs; that on the contrary the southern end of Florida is built up on successive concentric barrier-reefs which have been gradually connected and cemented into continuous dry land by the accumulation of mud-flats between them, and that this process is still going on and must eventually convert the present keys and reefs from Cape Florida to the Tortugas into similar land.[1]

In 1863 Prof. Carl Semper published the results of his researches among the Pelew Islands. He found himself unable, by the theory of subsidence, to account for the phenomena there presented, and threw doubts on the general applicability of that theory. He pointed out that while the southern islands, probably once atolls, consist of coral-rock, upraised to from 400 to 500 feet above the sea, and are flanked by living coast-reefs, true living atolls exist at the northern end of the group. He contended that there is absolutely no evidence of subsidence, that the association of all the different kinds of reefs within so circumscribed an area seems entirely to disprove the notion of subsidence, and that, at least in this group of islands, Darwin's theory cannot be applied. In some suggestive observations on their probable origin, he remarks that the reefs depend mainly for their form upon the nature of the bottom on which they begin. Atolls are formed on submarine banks. A species of *Porites* takes root in little colonies varying from the size of the fist to masses six or eight feet in diameter. In time the central portions of these growing colonies die, while the outer parts flourish and gradually build up a ring of coral. This ring, which may be circular or elongated in form, is sometimes continuous, but more commonly is traversed by one or more channels. The interior portions are scoured out and deepened by the tidal currents. Or if the form of the bottom and other conditions be suitable, a great many individual masses of coral gradually grow into a more or less continuous reef, through which the strong ebb and flow of the tides serve to keep open some channels. Thus fringing-reefs, through the scour of the sea, become barrier-reefs, which retreat from the adjacent coast in proportion to the gentleness of the slope on which they are built. On a steeply shelving sea-bottom the reefs must obviously remain fringing-reefs.

[1] The narrative containing Prof. Dana's observations on coral-reefs was published among the Reports of the Expedition. In 1872 he published a volume on "Coral and Coral-Reefs," where he again gave the weight of his authority to the theory of subsidence.

[2] *Boston Journ. Nat. Hist.*, iv. (1843-44), p. 137.

Dr. Semper admitted that possibly many atolls and barrier-reefs were formed during subsidence, and even that the downward movement may in many cases have furnished the conditions for starting them into existence. The solution of the problem ought in each case, he thought, to be determined by actual detailed observation. But that the alternate currents of the tides are the main agents in the building of coral-reefs could be proved, he maintained, by many cases which, on the theory of subsidence, must be regarded as exceptional or inexplicable, such as the occurrence of true atolls in the midst of areas of elevation.[1]

In the second edition of his "Coral Islands," published in 1874, Darwin briefly referred to these observations. He thought it not improbable that the Pelew Islands originally subsided, were afterwards upraised, and again subsided, but admitted that the proximity of fringing-reefs was opposed to his views. He suggested that if the submarine slope were steep reefs which began as fringing-reefs would continue to be of that form, even during subsidence. There is, however, no admission that any valid objection had been made to his theory, or that true atolls and barrier-reefs might be formed in many places without subsidence.

In 1868 Prof. Semper reiterated his dissent from the prevailing theory of coral-reefs.[2] Next year he reprinted his original paper (which seemed to him to have remained unknown to most naturalists) in a general account of the Philippine Islands, wherein he appended some additional notes.[3] In one of these he refers to the observations of Pourtales and others on a submarine calcareous deposit which in some regions is slowly being upraised to serve as a foundation for coral-reefs. To the objection that if atolls and barrier-reefs could be formed during a period of elevation, they ought to be found not merely at, or only slightly above sea-level, he replies that they are not in fact confined to that limited zone, but that even if they were, this would not invalidate his conclusion that the reefs are due to a complex cooperation of coral-growth with the waves and currents of the sea, and not to the one cause—the subsidence of entire regions—invoked by Darwin.

In the following year another contribution to the anti-subsidence literature was made by Dr. J. J. Rein, who, in an interesting memoir on the physical geography of Bermuda, offered some observations on the coral-reefs of those islands.[4] He suggested that the Bermuda group might originally have been a submarine mountain or bank on which colonies of deep-water corals took root, and where other organisms flourished in such abundance as gradually to raise the top of the submerged ground to the zone in which reef-building corals could flourish. He adduced no evidence in support of this suggestion further than that there is no proof in Bermuda of subsidence, which, however, as Darwin had so cogently shown, from the very fact of the movement being downward, is in most cases not to be looked for.

An important memoir, marking a totally new departure in coral-reef literature, appeared in 1880 containing an abstract of observations made by Mr. Murray during the great voyage of the *Challenger*.[1] The chief features of this contribution may be thus briefly summarised :—With hardly an exception the oceanic islands are of volcanic origin, and it is therefore to be presumed that the submarine ridges and peaks, which rise to within various distances from the surface, are likewise due to the protrusion of volcanic materials. There is thus no actual evidence of the still unsubmerged portions of any extensive continent or mass of land such as Darwin's theory requires. Whether built up above the sea-level into islands, or brought up to varying heights below that level, the volcanic eminences of the ocean may conceivably be brought into the condition of platforms for reef-builders by two causes. In the first place the erosive force of waves and tidal scour must tend to reduce all prominent oceanic summits to the lower limit of breaker-action, and thereby to produce truncated cones or flattened domes and ridges on which coral-reefs, if not already established, might spring up. In the second place, submarine eminences may have been brought up to within the zone of the reef-builders by the deposit of organic detritus upon them. One of the most remarkable results of recent deep-sea exploration has been the accumulated evidence of the extraordinary profusion of pelagic life in the tropical surface waters. From experiments made during the cruise of the *Challenger*, Mr. Murray estimated that, if the organisms are as numerous down to a depth of 100 fathoms as they were found to be in the track of the tow-net, there must be more than sixteen tons of carbonate of lime in the form of calcareous shells in the uppermost hundred fathoms of every square mile of ocean. The shells and skeletons of these organisms fall in a constant rain to the bottom, where they supply some of the food needed by the fauna which there subsists upon the mud. By the accumulation partly of these superficial exuviæ, partly of the remains of the creatures living at the bottom, an organic deposit is growing over the sea-floor in the tropical regions wherein coral-reefs flourish. Owing probably to the greater solvent action of the increased proportion of carbonic acid in sea-water at great depths, or to the greater mass of water through which they must sink, the shells of the upper waters seem never to reach the bottom or at least soon disappear from it, for they are seldom met with in deep dredgings. But in shallower portions of the ocean they abound. Consequently it may be legitimately inferred that the rate of growth of the calcareous organic deposit on the sea-bottom must be more rapid in the shallower waters. The tops of submarine peaks and banks, being constantly heightened from this cause, will in course of time be brought up to a depth at which sponges, hydroids, deep-sea corals, annelids, alcyonarians, mollusks, polyzoa, echinoderms, and other organisms can flourish abundantly. When this has taken place, the upward growth of the calcareous formation will be accelerated by the accumulation of the remains of this abundant fauna as it lives and dies on the bottom. At last the zone of reef-building corals will be reached, and thereafter a growth of coral-rock will bring the sea-floor up to the level of low water. That coral-reefs undistinguishable from barrier-reefs and even atolls might be formed upon banks of sediment in a deep sea was admitted by Darwin.[2] But the assumption of so many submerged banks as this explanation would require, seemed to him so improbable that he dismissed it from further consideration. He was not aware, however, of the enormous abundance of minute calcareous organisms in the surface waters and of the comparative rapidity with which these remains might be accumulated on the sea-bottom.

[2] "Coral Islands," 2nd edit. p. 118.

Reef-builders starting on a submarine bank, whether prepared for them by erosion, by subsidence, or by the upward growth of organic deposits, would form reefs that must necessarily tend to assume the atoll form The central portions of the colony or clump of coral will gradually be placed at a disadvantage as compared with the peripheral parts of the mass in being further removed from the food-supply, and will consequently dwindle and die. In proportion as the reef approaches the sea-level these central parts are brought into increasingly uncongenial conditions, until at last an outer ring of vigorous, growing coral-reef encircles an inside lagoon overlying the central stunted and dead portions. The possibility of such a sequence of events was likewise recognised by Darwin. "If a bank, either of rock or of hardened sediment," he says, "lay a few fathoms submerged, the simple growth of the coral, without the aid of subsidence, would produce a structure scarcely to be distinguished from a true atoll."[1]

As the atoll increases in size the lagoon becomes proportionately larger, partly from its waters being less supplied with pelagic food and therefore less favourable to the growth of the more massive kinds of coral, partly from the injurious effects of calcareous sediment upon coral-growth there, and partly also from the solvent action of the carbonic acid of the sea-water upon the dead coral. The solution of dead calcareous organisms by sea-water is undoubtedly one of the most interesting facts brought to light by the naturalists of the *Challenger* Expedition.

Moreover, a connected chain of atolls might be formed on a long, submarine bank, and similar conditions of growth would then be displayed as in the case of a single atoll. The marginal atolls having a better supply of food would grow more vigorously than those towards the centre, and would tend to assume elongated forms, according to the shape of the bank beneath them. Many of them might coalesce, and might even ultimately give rise to one large atoll. Such a chain of atolls as that of the great Maldive group may be thus explained without the necessity for any disseverment by oceanic currents as Darwin supposed. On the other hand, the submerged coral-banks of the Lakadivh, Caroline, and Chagos archipelagos may be regarded as representing various stages in the growth of coral-reefs, some of them being still too deep for reef-builders, others with coral-reefs which have not yet quite grown up to the surface. But scattered among these banks are some of the most completely formed atolls. Mr. Murray contends that it is difficult to conceive how such banks can have been due to subsidence, when their situation with respect to each other and to the perfect atolls is considered. He reverses the order of growth as given by Darwin, who cited the great Chagos bank as probably an example of an atoll which had been carried down by a subsidence more rapid than the rate at which the corals could build upwards.

From a careful study of barrier-reefs Mr. Murray concludes that, in their case also, all the phenomena can be explained without having recourse to subsidence. He found from personal observation and a comparison of the Admiralty charts that most exaggerated notions prevail regarding the depth of water immediately outside the reef, which is usually supposed to be very great. After minutely exploring the barrier-reef of Tahiti, and sounding the water both inside and outside the reefs, he found that the slopes are just such as might be looked for on the supposition that the corals have grown up without any sinking of the bottom. The accompanying section (Fig. 1), drawn to a true scale will show that there is nothing abnormal in the declivities. Beginning near the shore or wherever the bottom whether of rock or sediment comes within the range of the reef-builders, a barrier-reef grows vigorously along its outer face, while its inner parts, as in the case of an atoll and for the same reason, are enfeebled and die. The force of the breakers tears off huge masses, sometimes 20 or 30 feet long, from the face of the reef, especially where from the borings of mollusks, sponges, &c., the coral-rock has been weakened. These blocks tumble down the seaward face of the reef, forming a remarkably steep talus. It is this precipitous part of the reef which has probably given rise to the notion that the water outside suddenly descends to a profound depth. The steep front of fallen blocks is succeeded by a declivity covered with coral sand, beyond which the bottom slopes away at an angle of no more than 6°, and is covered chiefly with volcanic detritus. Mr. Murray insists that any seaward extension of the reef must be on the summit of the talus of broken coral. The reef will gradually recede from the shore of the island or continent, and will leave behind here and there a remnant to form an island in the slowly broadening lagoon-channel.

The very general occurrence of proofs of elevation among the regions of barrier-reefs and atolls is in harmony with the volcanic origin of the ground on which these coral-formations have grown, but is, as Mr. Murray contends, most difficult of explanation on the theory of widespread subsidence. He affirms that all the chief features of coral-reefs and islands not only do not necessarily demand the hypothesis of subsidence, but may be satisfactorily accounted for, even in areas where the movement is an upward one, by the vigorous outward growth of the corals on the external faces of the reef in presence of abundant food, by their death, disintegration, and removal by the mechanical and chemical action of the sea in the inner parts, and by the influence of subaërial agencies and breaker-action in lowering the level of the upraised areas of coral-rock.

ARCH. GEIKIE

(*To be continued.*)

NOTES

It will be seen from our Diary that the meeting of the Linnean Society on December 6 is to be exclusively devoted to the reading of a posthumous essay on Instinct by the late Mr. Darwin. We are informed that this essay is full of important and hitherto unpublished matter with regard to the facts of animal instinct considered in the light of the theory of natural selection; and as the existence of the essay has only now been divulged, we doubt not that the next meeting of the Linnean Society will be of an unusually interesting character.

The death is announced, at the age of seventy-six, of Mr. John Eliot Howard, F.R.S., well known as a chemist and quinologist. He was the son of Mr. Luke Howard, F.R.S., a well-known meteorologist in his day.

We announced some time ago that the Finnish Senate had voted a sum of 37,000 marks to Prof. Lemström for the continuation of his experiments with the aurora borealis at Sodankylä in the Finnish Lappmark during 1882-83, of which he gave an account in NATURE (vol. xxvii. p. 389). The plan to be followed during the present winter at this station is to make observations three times in every twenty-four hours, with the exception only of the first and fifteenth of every month, when they are made every five minutes throughout the twenty-four hours, and three days of the month when they will be effected every half minute during two hours. In order partly to obtain the necessary data for the control of the variation of the current from the atmosphere with the latitude, and partly to reduce the effect of probable influences, a branch station will be temporarily established during the months of November, December, January, February, and part of March at the buildings of the Kultala gold works, some distance from the principal station at Sodankylä. At Kultala exhaustive experiments will be made as to the effect which the increase of the area of the "utströmnings" apparatus, invented by Prof. Lemström for producing the aurora borealis, has on the intensity of the current. The observations will in other respects be the same at both stations. At Sodankylä they will be continued until September 1, 1884.

---

[1] *Op. cit.* p. 134.

THE Report by the Board of Trade on their Proceedings and Business under the Weights and Measures Act, 1878, for the past year has been issued. The following are some of the leading points in the Report: During the past year the Standards Department has had the opportunity of assisting the United States Government in a comparison of their standard of length (Yard No. 57), with the standards at this office. Prof. C. S. Peirce, of the United States Coast and Geodetic Survey, came to London for this purpose in June last, on behalf of Prof. J. E. Hilgard, who has charge of the Bureau of Weights and Measures at Washington. A large number of comparisons of these measures was made with all possible care, and it was found that at 62° F., Yard No. 57 was 0·000022 inch longer than the Yard No. 1 deposited at this office. The results of these comparisons, as calculated by Prof. Peirce, will be referred to in a printed memorandum which will be separately drawn up. It was found necessary to test the accuracy of the standard kilogram, and the only resource was to apply to the Comité International des Poids et Mesures for permission to compare the British standard kilogram with that deposited at their bureau near Paris. By the report of this comparison, it is seen that our standard kilogram is now 2·0178 milligrams too light. The Report rather naïvely points out that, but for the courtesy of the Comité, the Standards Department would have been unable to re-verify our unit of metric weight, as this country is not represented on the Comité, and consequently does not contribute towards its expenses. In a previous Report it is also pointed out that the Board of Trade had been then able to avail itself of the results of the scientific researches which had been carried out under the directions of the Bureau. A note on the instrumental equipment of the Bureau of the Comité International is attached to the Report; of the equipment of this Bureau we recently gave a detailed description. The tables of densities and expansions hitherto in use at the Standards Office not having been found entirely in accord with the most recent scientific research, new tables have been drawn up for future use in the accurate comparisons of standards of measure and weight, and these are given in the Appendix. At the last annual trial of the pyx, the Report states, the differences in weight and fineness of the new coins then submitted for testing were again found to be far within the legal amounts allowed, *particularly on those allowed in the fineness of the gold coin.* With reference to the Electric Lighting Act, the Report remarks that with the advance of science there arise from time to time measures and weights of new forms and denominations which, in their application to commercial purposes, subsequently receive the sanction and force of legislative enactment. Among the most important of such new measures are those for the measurement of mechanical and of electrical energy, as applied to the measurement of electricity under the Electric Lighting Act of last year. A present unit of measurement has been taken in Provisional Orders under this Act, which is equivalent to "the energy contained in a current of 1000 amperes flowing under an electromotive force of one volt during one hour." No practical meter of electricity capable of use in commerce and daily life has yet received official sanction. The Report and Appendices show that Mr. Chaney continues the work of his office as efficiently as his means will permit.

AT the last sitting of the Academy of Sciences M. Pasteur read and commented on a posthumous paper by Dr. Thuilier his pupil, who died in Alexandria, where he was sent in August, in order to make observations on cholera. The late Dr. Thuilier takes an intermediate position between M. Pasteur and M. Bouchardat. M. Pasteur seems not to be quite opposed to the views of his pupil.

THE German Cholera Commission are going, not, as they originally intended, to Bombay, but to Calcutta, as they consider the latter place more suitable for their investigations.

IN an official pamphlet published at Washington there is an interesting sketch of the work and history of the United States Bureau of Education. Not only does the Bureau publish reports on education in the United States, but at frequent intervals issues "Circulars of Information" containing data of great value, and in many cases not otherwise accessible. Among other things these circulars contain information on the systems of education in nearly every civilised country, including China; the pamphlet referred to contains a useful list of all the circulars issued, with their contents.

IN the report by Dr. Daniel Draper on the New York Meteorological Observatory for 1882, it is shown that the actual hours of sunshine at Greenwich Observatory were 1245 in 1878 and 977 in 1879, when the possible hours were 4447; whereas at New York in the former year the actual hours were 2936, and in the latter 3101, when the possible hours were 4449.

THE "Howard" Medal of the Statistical Society for 1883, with a prize of 20*l*., has been awarded to Dr. R. D. R. Sweeting, S.Sc. Cert. Camb., Medical Superintendent of the Western District Fever Hospital, Fulham, for the best essay on "The experiences and opinions of John Howard on the preservation and improvement of the health of the inmates of schools, prisons, workhouses, hospitals, and other public institutions, as far as health is affected by structural arrangements relating to supplies of air and water, drainage," &c.

THE cultivation of Sorghum (*S. saccharatum*) and the manufacture of sugar from its stems has of late occupied a large share of attention by the Government in America, reports on which have been issued at different times. The most recent of these is an "Investigation of the Scientific and Economic Relations of the Sorghum Sugar Industry." This is in the form of a report drawn up by the committee of the National Academy of Sciences, in which the subject of the cultivation, production, and manufacture of the sugar is treated in considerable detail. The report is one of considerable value, especially to those interested in the progress of this industry.

FROM Dr. King's Annual Report of the Royal Botanic Garden, Calcutta, for the year 1882-83, and Mr. J. F. Duthie's Report of the Government Botanical Gardens at Saharunpur and Mussoorie for the year ending March 31, 1883, both of which have recently reached us, we learn something of the progress of botany at these botanical centres in India. It is satisfactory to note that at Calcutta considerable improvements have been effected during the year, not only in the general arrangements of the garden itself but also in the scientific department, for Dr. King informs us that "the bamboo and mat erections which used to do duty as conservatories have been replaced by three large, handsome, and efficient structures of iron, on which a thin thatch of grass is spread, and under shelter of which tropical plants thrive admirably." As usual at Calcutta considerable attention has been given to various economic plants, notably those which produce the valuable article indiarubber, and which have occupied so much attention of late. Dr. King says the cultivation of the soy bean of Japan (*Glycine soja*) has of late been pressed on the people of India, and "more in obedience to the loudness o this clamour than from a belief in its soundness" he has arranged for a supply of the beans from Japan, which he proposes to distribute extensively for trial. Much consideration has also been given to the utilisation of the various fibrous plants. In the Lloyd Botanic Garden, Darjeeling, much damage continued to be done by the cockchafer grubs until pretty nearly every plant in the garden was killed. "The whole of the grass in the garden and all herbaceous plants rapidly succumbed to its ravages, as did many of the flowering shrubs, only the deeper rooting shrubs and trees being spared. Even the plants in the conservatories did not altogether escape; eggs of the insect having got in considerable numbers into the soil of the pots." In response to vigorous efforts to exterminate this plague about six millions of the grubs were collected and destroyed by the garden labourers, so that at the time of writing the Report it was showing signs of disappearing. In Mr. Duthie's Report it is satisfactory to find that economic plants, as at Calcutta, are largely cared for, and that the cultivation of medicinal plants and the preparation of drugs from them is being proceeded with. Amongst these may be mentioned Alexandrian senna (*Cassia acutifolia*), henbane (*Hyoscyamus niger*), belladonna (*Atropa belladonna*), &c. Additions are also being constantly made to the museum.

PART VI. of the "Herefordshire Pomona" has been issued, and Part vii. and last will be published in the autumn of next year, after the Congress and Exhibition of the Pomological Society of France, to be held at Rouen in October.

IN the *Japan Mail* of August 23 and September 24, Mr. E. Knipping describes the course of two storms which occurred, one on August 17 to 20, and the other September 11 to 14. These descriptions show how very completely the Japan meteorological service is organised, and that good work is being done in the Far East in collecting data for scientific meteorology.

MESSRS. MACMILLAN AND CO. have published as one of their "NATURE Series" volumes, Drs. Gladstone and Tribe's "Chemistry of the Secondary Batteries of Planté and Faure." "About Photography and Photographers" is the title of an interesting gossipy little volume by Mr. H. Baden Pritchard, published by Messrs. Piper and Carter.

MISS J. M. HAYWARD wishes to state with reference to Mr. Denning's letter (p. 56) that she did give the hour (10.30) at which her letter was written, with the date, at the end. She adds that a clock struck ten shortly before she saw the meteor; but she thinks the clock was probably slow, as it generally is. She has no doubt it was the same meteor as that seen at Bath, Bristol, and Chelmsford about the same time.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus sinicus*) from India, presented respectively by Mr. H. G. Rose and Miss Morant; a Common Fox (*Canis vulpes*), British, presented by Mr. H. Vaughan; two Bullfinches (*Pyrrhula europæa*), European, presented by Mr. Archibald Aitchison; four Moorish Toads (*Bufo mauritanicus*) from Tunis, presented by Mr. Frederick Bridges; twelve Ruffe, or Pope (*Acerina cernua*) from British waters, presented by Mr. T. E. Gunn; two Michie's Tufted Deer (*Elaphodus michianus* ♂ ♀), a Chinese Water Deer (*Hydropotes inermis*), two Elliot's Pheasants (*Phasianus ellioti*) from China, deposited; six Coal Titmice (*Parus ater*), British, purchased; a Spotted Ichneumon (*Herpestes nepalensis*) from Nepal, five Blue-crowned Hanging Parrakeets (*Loriculus galgulus*) from Malacca, received in exchange.

OUR ASTRONOMICAL COLUMN

PONS' COMET.—Mr. S. C. Chandler has communicated to the *Astronomische Nachrichten* his own experiences at the Observatory of Harvard College with reference to the remarkable increase in the brightness of this comet on September 22, which has been already mentioned in NATURE (vol. xxviii. p. 624). He observed with an aperture of 6¼ inches. On September 21, between 8h. 55m. and 11h. M.T. he found the comet very faint and diffuse; the central condensation or nucleus about equal to a star of 11 m. On September 22, about 7h. M.T. he was astonished to find exactly in its place a bright, clearly-defined 8 or 8¼ mag. star without sensible trace of nebulosity, except with a power of only 50, giving a field of 1¼ degrees, and even with that not noticeable except with attention. It was so distinctly stellar an object that an experienced observer might have failed to distinguish it from stars of similar brightness in the neighbourhood. On September 23, at 7h. 30m., he found the physical appearance again greatly changed. The nucleus seemed spread out into a confused bright disk about a half minute (arc) in diameter, outside of which was a nebulous envelope much brighter than on the preceding night, and about one minute and a half in diameter. The comet was judged to be a half magnitude brighter than on September 22. On September 25 it appeared spread out into a confused disk two minutes in diameter, a faint nucleus or concentration of light not brighter than 11 m. So rapid an increase and diminution of light is a very unusual phenomenon; Mr. Chandler thinks that phases of this kind may be characteristic of the comet's mode of light development, as the same variation was repeated on a smaller scale on October 15, when a nucleus of about 9·3 m. appeared, which gradually dissipated on the following evenings, through expansion into the general nebulosity. The comet's distance from the sun when Mr. Chandler remarked the great increase of brightness was 2·18, the earth's mean distance being taken as unity, not the least surprising condition in the case.

In the same number of the *Astronomische Nachrichten* Prof. Schiaparelli gives some account of his observations on the physical appearance of the comet at Milan, which are of much interest in connection with those of Mr. Chandler. On September 22 he found the comet about 3′ in diameter, faint and diffuse, the nucleus about 13m., but the sky was not perfectly clear; the observations for position were made at 8h. 30m. M.T. On September 23, about 8h. 13m., the comet had increased in brightness since the previous evening in an extraordinary manner; it now appeared as a star of 8 m., with a very faint surrounding nebulosity of from 1′ to 1½′ diameter. The central part was not exactly a luminous point, but had a sensible diameter and indistinct outline. On the 25th it was still bright, but the nucleus of the 23rd had spread out so as to form a circular nebulosity 3′ in diameter, without notable central condensation.

Comparing the Milan and Harvard observations, it would appear that the rapid increase in the light of the comet took place between September 22, at 7h. 45m. and 11h. 45m. Greenwich mean time; it remains to be seen how observations elsewhere will accord with this inference. Mr. Chandler suspected, from a comparison of his own notes with those made by the observers at Kiel and Vienna, that the increase would be found to have taken place between the European and American observations on September 22.

M. Bigourdan, of Paris, says on November 19, "The comet is a nebulosity of from sixth to seventh magnitude, with nucleus: the brightest part of the coma, that which borders on the nucleus, is not symmetrical about it; it is less extended in the angle 110°—140°, and is brightest in the angle 280°—290°." Taking the comet's theoretical intensity of light on November 19 as unity, the intensity on December 31 will be 9·5, and on January 14 (when it is at its maximum), 13·0. In the absence of moonlight the comet must be, for some time, a naked eye object.

THE GENERAL THEORY OF THERMO-DYNAMICS

THE first of the six lectures on "Heat in its Mechanical Applications" at the Institution of Civil Engineers was delivered on November 15 by Prof. Osborne Reynolds, M.A., F.R.S., the subject being as given in the title. The following is an abstract of the lecture:—

Thermodynamics, Prof. Reynolds said, was a very difficult subject. The reasoning involved was such as could only be expressed in mathematical language; but this alone would not prevent the leading facts and features of the subject being expressed in popular language. The physical theories of astronomy, light, and sound involved even more mathematical complexities than thermodynamics, but these subjects had been rendered popular, and this to the great improvement of the theories.

What rendered the subject of thermodynamics so obscure was that it dealt with a thing or entity (heat) which, although its effects could be recognised and measured, was yet of such a nature that its mode of operation could not be perceived by any of our senses. Had clocks been a work of nature, and had the mechanism been so small that it was absolutely imperceptible, Galileo, instead of having to invent a machine to perform a definite function, would have had, from the observed motion of the hands, to discover the mechanical principles and actions involved. Such an effort would have been strictly parallel to that required for the discovery of the mechanical principles of which the phenomena of heat were the result.

In the imagined case of the clock, the discovery might have been made in two ways. By the scientific method: from the observed motion of the hands the fact that the clock depended on a uniform intermittent motion would have led to the discovery of the principle of the uniformity of the period of vibrating bodies; and on this principle the whole theory of dynamics might have been founded. Such a theory of mechanics would have been as obscure but not more obscure than the theory of thermodynamics based on its two laws. But there was another method; and it was by this that the theory of dynamics was brought to light—to invent an artificial clock, the action of which could be seen. It was from the actual pendulum that the principles of the constancy of the periods of oscillating and revolving bodies were discovered, whence followed the dynamical theories of astronomy, of light, and of sound.

As regarded the action of heat, no visible mechanical contrivance was discovered which would afford an example of the mechanical principles and motions involved, so that the only apparent method was to discover by experiment the laws of the action of heat, and to accept these as axiomatic laws without forming any mental image of their dynamical origin. This was what the present theory of thermodynamics purported to be.

In this form the theory was purely mathematical and not fit for the subject of a lecture. But as no one who had studied the subject doubted for one moment the mechanical origin of these laws, Prof. Reynolds would be following the spirit if not the letter of his subject, if he introduced a conception of the mechanical actions from which these laws sprang. This he should do, although he doubted if he should have so ventured, had it not been that while considering this lecture he hit upon certain mechanical contrivances, which he would call kinetic engines, which afforded visible examples of the mechanical action of heat, in the same sense as the pendulum was a visible example of the same principles as those involved in the phenomena of light and sound. Such machines, thanks to the ready help of Mr. Foster his assistant in constructing the apparatus, he should show, and he could not but hope that these kinetic engines might remove the source of the obscurity of thermodynamics on which he had dwelt.

The general action of heat to cause matter to expand was sufficiently obvious and popularly known; also that the expanding matter could do work was sufficiently obvious. But the part which the heat played in doing this work was very obscure.

It was known that heat played two, or it might be said three, distinct mechanical parts in doing this work.

These parts were:—

1. To supply the energy necessary to the performance of work.

2. To give to the matter the elasticity which enabled it to expand—to convert the inert matter into an acting machine.

3. To convey itself, *i.e.* heat, in and out of the matter.

This third function was generally taken for granted in the theory of thermodynamics, although it had an important place in all applications of this theory.

The idea of making a kinetic engine which should be an example of action such as heat, had no sooner occurred to him than various very simple means presented themselve. Heat was transformed by the expansion of the matter caused by heat.

At first he tried to invent some mechanical arrangement which would expand when promiscuous agitation was imparted to its parts, but contraction seemed easier—this was as good. All that was wanted was a mechanism which wou'd change its shape, doing work when its parts were thrown into a state of agitation.

In order to raise a bucket from a well either the rope was pulled or the windlass wound—such a machine did not act by promiscuous agitation; but if the rope was a heavy one (a chain was better) and it was made fast at the top of the well so that it just suspended the bucket, then if it was shaken from the top waves or wriggles would run down the rope until the whole chain had assumed a continually changing sinuous form. And since the rope could not stretch, it could not reach so far down the well with its sinuosities as when straight, so that the bucket would be somewhat raised and work done by promiscuous agitation. The chain would have changed its mechanical character, and from being a rigid tie in a vertical direction would possess kinetic elasticity, *i.e.* elasticity in virtue of the motion of its parts, causing it to contract its vertical length against the weight of the bucket. Now it was easy to see in this case that to perform this operation the work spent in shaking the rope performed the two parts of imparting energy of motion to the chain and raising the bucket. A certain amount of energy of agitation in the chain would be necessary to cause it to raise a bucket of a certain weight through a certain distance, and the relation which the energy of agitation bore to the work done in raising the bucket followed a law which if expressed would coincide exactly with the second law of thermodynamics. The energy of agitation imparted to the chain was virtually as much spent as the actual work in raising the bucket, that was to say, neither of these energies could be used over again. If it was wanted to do further work the raised bucket was taken off, and then to get the chain down again it must be allowed to cool, *i.e.* the agitation must be allowed to die out; then attaching another bucket, it would be necessary to supply the same energy over again.

He had other methods besides the simple chain which served better to illustrate the lecture, but the principle was the same.

In one there was a complete engine with a working pump. By mere agitation the bucket of the pump rose, lifting 5 lbs. of water one foot high; before it would make another stroke the agitated medium must be cooled, *i.e.* the energy which caused the elasticity must be taken out, then the bucket descended, and, being agitated again, made another stroke.

He felt that there was a childish simplicity about these kinetic engines, which might at first raise the feeling of "Abana and Pharpar" in the minds of some of his hearers. But this would be only till they realised that it was not now attempted to make the best machine to raise the bucket, but a machine that would raise the bucket by shaking. These kinetic engines were no mere illustrations or analogy of the action of heat, but were instances of the action of the same principles. The sensible energy in the shaking rope only differed in scale from the energy of heat in a metal bar. The temperature of the bar, ascertained from absolute zero, measured the mean square of the velocity of its parts multiplied by some constant depending on the mass of these parts. So the mean square of the velocity of the links of the chain multiplied by the weight per foot of the chain really represented the energy of visible agitation in the chain.

The waves of the sea constituted a source of energy in the form of sensible agitation; but this energy could not be used to work continuously one of these kinetic machines, for exactly the same reason as the heat in the bodies at the mean temperature of the earth's surface could not be used to work heat-engines.

A chain attached to a ship's mast in a rough sea would become elastic with agitation, but this elasticity could not be used to raise cargo out of the hold, because it would be a constant quantity as long as the roughness of the sea lasted.

Besides the waves of the sea there was no other source of sensible agitation, so there had been no demand for kinetic engines. Had it been otherwise, they would not have been left for him to discover—or, had they been, he might have been tempted to patent the inventions. But there had been a demand for what might be called sensible kinetic elasticity to perform for sensible motion the part which heat-elasticity performed in the thermometer.

And it had not been left for him to invent kinetic mechanism for this purpose, although it might be that its semblance to the thermometer had not been recognised. The principle was long ago applied by Watt. The common form of governors of a steam-engine acted by kinetic elasticity, which elasticity, depending on the speed at which the governors were driven, caused them to contract as the speed increased. The governor measured by contraction the velocity of the engine, while the thermometer measured by expansion the velocity in the particles of matter which surrounded it; so that it could now be seen that having to perform two operations, the one on a visible scale, the other on a molecular scale, the same class of mechanism had been unconsciously adopted in performing both operations.

The purpose for which these kinetic engines was put forward was not that they might be expected to simplify the theory of thermodynamics, but that they might show what was being done. The theory of thermodynamics could be deduced by the laws of motion from any one of these kinetic engines, just as Rankine deduced it from the hypotheses of molecular vortices.

Nothing had yet been said of the third part which heat played in performing work, namely, conveying heat in and out of matter. It was an innovation to introduce such considerations into the subject of thermodynamics, but it properly had a place in the theory of heat-engines. It was on this part that the speed at which an engine would perform work depended.

The kinetic machines showed this. If one end of a chain was shaken, the wriggle ran along with a definite speed, so that a definite interval must elapse before sufficient agitation was established to raise the bucket; further, an interval must elapse before the agitation could be withdrawn, so that the bucket might be lowered for another stroke. The kinetic machine, with the pump, could only work at a given rate. He could increase this rate by shaking harder, but then he expended more energy in proportion to the work done. This exactly corresponded with what went on in the steam-engine, only owing to the use of separate vessels, the boiler, cylinder, and condensers, the connection was much confused. But it was clear that for every h.p. (2,000,000 ft.-lbs. per hour) 15,000,000 ft. lbs. had to be passed from the furnace into the boiler, as out of the 15,000,000 no more than 2,000,000 could be used for work; the remaining 13,000,000 were available for forcing the heat into the boiler and out of the steam in the condenser, and they were usefully employed for this purpose.

The boilers were made as small as sufficed to produce steam, and this size was determined by the difference of the internal temperatures of the gases in the furnaces, and the water in the boiler; and whatever diminished this difference would necessarily increase the size of the heating surface required, *i.e.* the weight of the engine. The power which this difference of temperature represented could not be used in the steam-engine, so it was usefully employed in diminishing the size of the engine.

Most of this power, which in the steam-engine was at least eight times the power used, was spent in getting the heat from the gases into the metal plates, for gas acted the part of conveyance far less readily than boiling water or condensing steam. If air had to be heated inside the boiler and cooled in the condenser with the same difference of temperature, there would be required thirty or forty times the heating surface—a conclusion which sufficiently explained why attempts to substitute hot air for steam had failed. In one respect the hot-air engines had an advantage over the steam-engine. During the operation in the cylinder the heat was wanted to be kept in the acting substance; this was easy with air, for it was such a bad conductor of heat, that unless it was in a violent state of internal agitation it would lose heat but slowly, although at a temperature of 1000 degrees and the cylinder cold.

Steam, on the other hand, condensed so readily that the temperature of the cylinder must be kept above that of the steam. It was this fact which limited the temperature at which steam could be used. Thus, while hot air failed on account of time economy, the practical limit of the economy of steam was fixed by the temperature which a cylinder would bear. These facts were mentioned because at the present time there appeared to be the dawn of substituting combustion-engines in place of steam-engines.

Combustion-engines, in the shape of guns, were the oldest form of steam-engine. In these, the time required for heating the expansive agent was zero, while they had the advantage of incondensible gas in the cylinder, so that if the cylinder was kept cool it cooled the gas but slightly, although this was some 3000 degrees in temperature.

The disadvantage of these engines was that the hot gas was not sufficiently cooled by expansion, but a considerable amount of the heat carried away might be used again could it be extracted and put into the fresh charge; to do this, however, would introduce the difficulty of heating-surface in an aggravated form. However, supposing the cannon to have been tamed and coal and oxygen from the air to be used instead of gunpowder. Thermodynamics showed that such engines should still have a wide margin of economy over steam-engines, besides the advantage of working with a cold cylinder and at an unlimited speed. The present achievement of the gas-engine, stated to be some 2,000,000 ft.-lbs. per lb. of coke, looked very promising, and it was thus not unimportant to notice that whatever the art difficulties might be, thermodynamics showed no barrier to further economy in this direction, such as that which appeared not far ahead of what was already accomplished with steam-engines.

But however this might be, he protested against the view which seemed somewhat largely held that the steam-engine was only a semi-barbarous machine, which wasted ten times as much heat as is used—very well for those who knew no science, but only waiting until those better educated had time to turn their attention to practical matters, and then to give place to something better. Thermodynamics showed the perfections not the faults of the steam-engine, in which all the heat was used, and could only enhance the admiration in which the work of those must be held who gave, not only the steam-engine, but the embodiment of the science of heat.

PROFESSOR AUGUST WEISMANN ON THE SEXUAL CELLS OF THE HYDROMEDUSÆ[1]

PROF. WEISMANN of Freiburg is most highly skilled and most indefatigable in research, and all the memoirs which he publishes are of extreme scientific importance, and abound in original views and suggestions which render them of peculiar and widely spread interest. His "Studien zur Descendenz Théorie," his researches on the Daphnoids and on the fauna of Lake Constance, which are known to all naturalists, may be mentioned as examples of his work. Since the spring of 1878 till the present year he has been engaged in investigating the mode of origin of the gonad elements of the Hydromedusæ, and the results are embodied in the present splendid work, which consists of a volume of text of about 300 pages quarto and twenty-four most beautifully executed coloured plates, the whole representing a vast amount of laborious research. Some portions of the results have already appeared in short preliminary papers, but they form a very small instalment of what is here put forth. In the course of the investigation, which has extended to thirty-eight species of Hydromedusæ, important new observations on the habits and composition of Hydroid colonies generally and on their histology were made, and the results of these are fully described here, since most of them have a direct bearing on the elucidation of the main subject of the monograph. The work thus forms secondarily, as stated in the title-page, "a contribution to the knowledge of the structure and vital phenomena of the Hydromedusæ generally."

The principal value of the work, however, lies in the importance of the bearings of the results of the investigations detailed in it upon the general question of the origin of gonad cells. The Hydromedusæ were selected as the subject of research because they appeared to be of all groups of the animal kingdom best adapted for the purpose both because of the transparent nature of their tissues and because they present in closely allied forms so many remarkable differences in the development of the gonad elements.

The work commences with an historical introduction, which can be but briefly referred to here. The question of the origin of the sexual elements in the Hydroida has undergone several important transformations. Prof. Huxley, when he first defined the body of the Medusa as consisting of two layers of tissue—ectoderm and endoderm, raised the question in which of the two layers do the gonad elements originate, and at first concluded that they were formed between the two, and subsequently in 1859, from physiological considerations mainly, that they must originate in the ectoderm. As soon as the advance of histological method permitted accurate direct observation to be made on the matter, Keferstein and Ehlers showed that in the Siphonophora with well developed medusoid sexual individuals, the Calycophoridæ and male Physophoridæ, the germinal cells are developed in what is now recognised as the ectoderm of the manubrium;

---

[1] "Die Entstehung der Sexualzellen bei den Hydromedusen." Zugleich ein Beitrag zur Kenntniss des Baues und der Lebenserscheinungen dieser Gruppe, von Dr. August Weismann, Professor in Freiburg-i-Br. (Jena: G. Fischer, 1883.)

whilst in the female Physophoridæ the origin of the single ovum is different (in the endocodon). As soon as the homogeny of the two layers of the Cœlenterata with the two primitive layers of the higher Metazoa became evident, the question arose whether the germinal cells of the Metazoa generally were of ectodermal or endodermal origin, and a large number of observers attempted to settle the question offhand by investigating the process of development of the germinal cells in some one Cœlenterate. Each assumed that his particular results must hold good for the entire group, and as the results were conflicting—the place of first appearance of the germinal cells lying as is well known in some Cœlenterates in the ectoderm and in others in the endoderm—much confusion arose. At this period, E. van Beneden's memoir appeared which, on the strength of the conditions occurring in a Hydractinia, a Campanularia, and a Clava, started the theory that the germ layers were themselves sexually differentiated, the female elements arising from the endoderm and the male from the ectoderm, and that in the union of a derivative of each layer lay the essence of impregnation, the necessary precursor of reproduction. This brilliant conception was soon shown by further observation to be erroneous, and as Prof. Weismann points out it was from the first not in accordance with the phenomena of parthenogenesis. As the next important phase in the question came the attempt of the brothers Hertwig to prove that the Cœlenterata belong to two distinct stocks, the one consisting of the Anthozoa and Scyphomedusæ, in which the germinal cells are derived from the endoderm (Endocarpæ), and the other of the Hydromedusæ and Ctenophora, in which they originate from the ectoderm (Ectocarpæ). If this position be correct, and, as will be seen in the sequel, one of the most startling of the conclusions arrived at in the present work is that, notwithstanding all the apparent evidence to the contrary, it probably is so in reality, then the important principle of inheritance and continuity in development in the germ layers receives a strong support, of which with regard to the gonad elements it seemed in great need. Prof Weismann was led to undertake the present prolonged researches by his observing that in certain of the Hydromedusæ the germinal cells originate, not in the sexual individuals themselves nor even in the blastostyles that support them, but in the cœnosarc of the colony, in the common parenchym of the stem and its branches, and that this occurs not only in the case of the female but also in some instances in that of the male germinal cells. The existence of ovicells of cœnosarcal origin had been previously observed by Quatrefages, F. E. Schultze, Fraipont, and others, but these elements had not been recognised as the sole source of supply of the female gonophores with ova. E. van Beneden further had observed the origin of the egg-cells in Hydractinia, in that part of the blastostyle which subsequently becomes evaginated to form the gonophore. Kleinenberg published his account of his discovery of the migration of the egg-cells of Eudendrium from the ectoderm into the endoderm and in the opposite direction just before Weismann had arrived at a similar conclusion and had found in his preparations egg-cells in the act of boring through the basement membrane with one half lying in the ectoderm and the other in the endoderm. The establishment of the fact that migration of the sexual cells of a most remarkable character in the many forms in which he has proved it to occur is a constant phenomenon, the history of its details, and the discussion of the phylogenetic origin and general biological bearings of the curious phenomena presented by it, form the most important features of the present work.

The author as more convenient adopts—instead of Allman's terms, phanerocodonic gonophore and adelocodonic gonophore—"medusa" and "medusoid gonophore" respectively. He applies the latter term to all gonophores, not becoming free medusæ, in the walls of which any traces, however rudimentary, can be detected of the three layers, viz. the inner and outer ectoderm layers and the intervening endoderm lamella—of which the wall of the bell of the medusa is composed. He uses the term sporophore for those gonophore sacs in which no indication of anything beyond a single layer of ectoderm and endoderm can be discovered.

A structure which assumes great importance in the history of the wanderings of the ovicells is the duplicature of ectoderm, which grows inwards at the summit of the simple sac-like bud out of which a medusa is formed, depressing the endoderm lamella and forming the hollow of the bell. It is necessary that this embryonic organ or mass of cells, observed by so many investigators, should receive a special name, and it is termed "endocodon."

It is pointed out that each hydranth of a colony does not consist alone of that part containing the stomach and bearing the tentacles and hypostome, but also of a stem-shaped portion, which is developed at the same time with it out of the same bud. This region is termed the "hydrocope," and is included in the hydranth, the remaining region of which is the "hydrocephalis." The hydrocope corresponds to the region in Tubularia which Allman terms hydrocaulus, but not to the whole system of stems and branches in an arborescent colony. In such colonies the production of buds is entirely confined to the hydrocope and its counterpart in the blastostyle, the "gonocope."

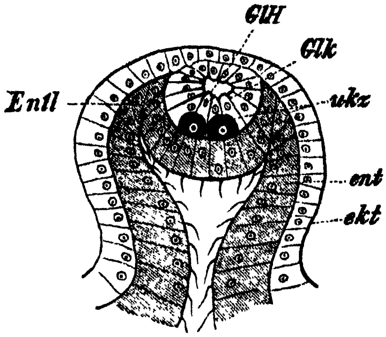

Fig. 1.—Diagram of a bud of a medusa or medusoid gonophore—*Glk*, endocodon; *GlH*, sub umbrella space; *Entl*, primitive endoderm lamella; *ukz*, primitive germ cells; *ent*, endoderm; *ekt*, ectoderm.

In the Tubularinæ it is necessary to distinguish amongst the hydranths of a stock the "principal" from the "lateral" hydranths. The principal hydranths are those which remain permanently at the extremities of the stems or branches throughout the growth of the stock by lateral budding. In the arborescent stocks of the Tubularidæ the first hydranth sprung from the egg remains permanently at the extremity of the

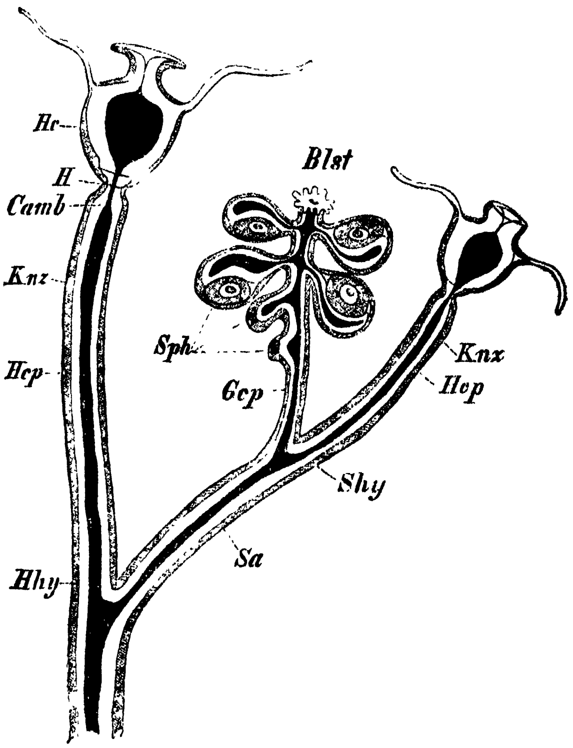

Fig. 2.—Diagram of a primary, *Hhy*, and lateral, *Shy*, hydranth of Eudendrium; *Hc*, hydrocephalis; *H*, neck; *Camb*, cambium zone; *Knz*, zone of gemmation; *Hcp*, hydrocope; *Sa*, lateral branch; *Blst*, blastostyle; *Gcp*, gonocope; *Sph*, sporophore.

principal stem, the lateral buds of which never surpass it in growth. In the same way the first formed hydranth of each lateral branch retains its position at the tip of that branch, and must be distinguished as a principal hydranth of secondary order, becoming such so soon as it produces a hydranth bud above its distal gonophore. This distinction is necessary not only because the primary and lateral hydranths often differ in size, but mainly from the most important fact that the principal hydranths are sexually sterile; only the lateral hydranths produce gonophores. No such distinction of principal hydranths occurs amongst the Campanularidæ and the Sertularidæ.

The above brief historical sketch and preliminary explanation is extracted from the introductory part of the work. The special part, which forms by far the greater portion of the whole, treats separately of the details of the series of species investigated.

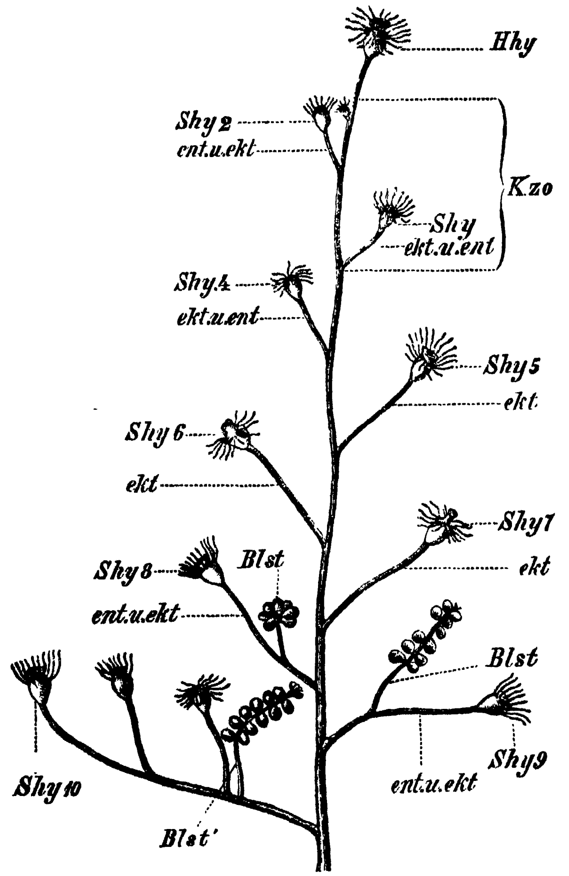

FIG 3.—Tip of a stem of *Eudendrium racemosum* (actual, not diagrammatic), with the principal hydranths, *Hhy*, and ten lateral hydranths, *Shy* 1-10; *Blst*, blastostyle, with female gonophores or ova; *Kzo*, germinal zone in wider sense, *i.e.* extent of the main stem and hydrocope containing egg-cells. The letters *ent* and *ect* indicate whether in the lateral hydrocopes of the specimen ovicells were present in the ectoderm or endoderm, or in both.

The results with regard to two of these forms, *Cordylophora lacustris* and *Eudendrium*, will be followed here, the former being chosen mainly because the account of it is illustrated by a woodcut, which it is advantageous to reproduce. The structure of *Cordylophora lacustris* is well known from F. E. Schulze's most excellent most excellent monograph. Weismann finds that the regular branching of the stock in this species depends on its following the law that "a principal or terminal hydranth of a principal stem or lateral branch produces no buds but those of hydranths, never those of gonophores, and that only the hydranths, and not the gonophores, can produce buds." The zone of gemmation of the hydranths lies in the hydrocope, just below the neck. In the female stocks the germinal cells do not take their origin in the gonophores, but arise in the cœnosarc in the ectoderm of the zone of gemmation of a principal hydranth and in this well defined and restricted region only.

The ovicells are certainly not preformed in the embryo or larva, but are formed in the zone before the lateral hydranth bud begins to appear out of ectoderm cells which differ in no respect from other young ectoderm cells. The ovicells migrate in the ectoderm from their place of origin to that where the bud of the lateral hydranth has begun to form, and, passing into the lateral hydrocope as it grows out, enter the gonophore as soon as it is developed, their entire course of travel lying in the ectoderm. Every ovicell becomes an ovum, and enough ovicells migrate in a group into the lateral hydranth to fill several gonophores; those not destined for the first formed gonophore move onwards past it, and a part of them pass later into the second gonophore when this becomes formed between the first and the neck of the lateral hydranth. This change of position of the ovicells must be partly due to active movement, since the simple shifting due to growth could not push the cells past the first gonophore, and long before the first gonophore is ripe these cells are found lying beyond it, whereas beforehand they lay below it (see Fig. 4, *wz*).

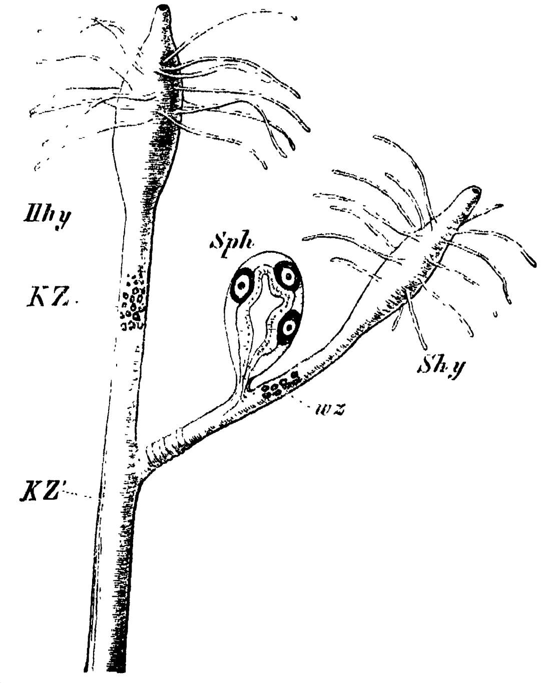

FIG 4—A principal hydranth, *Hhy*, and a lateral hydranth, *Shy*, of Cordylophora; *KZ*, actual germinal zone, also zone of gemmation; *KZ'*, former position of the germinal zone, *Sph*, female sporophore; *wz*, migrating ovicells.

The migration must take place very slowly and in a particular direction, for the cells are never found scattered irregularly along the whole stem, but always together in a small troop, and they never make their way by accident into a hydrocephalis. The same process is repeated in the formation of the second, and, if ovicells enough be present, of the third gonophore. A fresh swarm of ovicells is never introduced from the main stem into a lateral branch, and no new ovicells are developed in any lateral hydranth until it ceases to become such by developing a hydranth bud above its distal gonophore. It then becomes a principal hydranth of secondary order, and acquires at once a germinal zone beneath its neck, which supplies the gonophores developed on its lateral hydranth buds with ova by migration, just as in the case of the primary principal hydranth. It produces no further gonophores itself, and differs in no respect from the primary principal hydranth excepting in that it was once a lateral hydranth, and produced a set of gonophores, whilst the primary principal hydranth never was lateral and never produced gonophores. The ova ripen in the ectoderm of the sporophores.

The primitive male germinal cells in Cordylophora are formed like the female from young ectoderm cells, but their place of origin lies in the zone of gemmation of the lateral hydranth at the spot where the gonophore bud is formed.

In the genus Eudendrium most remarkably there is a difference in the formation of the gonad elements in the case of different species. In *Eudendrium racemosum* the gonophores are not borne by the hydranths but on blastostyles, which bud out only from the lateral hydranths. Both male and female germinal cells have their place of origin not in the gonophores or blastostyles, but in the cœnosarc; the gonophores are only the ripening places of the cells. The blastostyles are not regarded by the author as hydranths which in an ontogenetical sense become atrophied in the history of each colony, in consequence of the exhaustive effect of the development of gonophores on them, but as special structures probably derived originally from hydranths, but which have undergone a permanent phylogenetic modification (at all events in *E. racemosum* and *E. capillare*) to adapt them for their peculiar function. The developing buds from which blastostyles are formed are very early to be distinguished from those forming hydranths, and do not vary in colonies of the same sex, though they show a constant difference in form in the two sexes. The male blastostyles have no hypostome, mouth, or trace of tentacles. The female have also no hypostome but have a double crown of tentacles, and appear at the time when the gonophores are ripe to have a small temporary mouth, which it is suggested may possibly swallow the spermatozoa to effect fertilisation.

In the female stocks of *Eudendrium racemosum* when in full sexual maturity the cœnosarcal tubes at all the free ends of the branches contain large quantities of ovicells. The fine twigs are often full of hundreds of them. They occur in both ectoderm and endoderm, but far more abundantly in the former, where they are found in all stages of development, whereas in the endoderm scarcely any but large egg-cells are found. The primitive germinal cells are derived from ordinary young ectoderm cells, with which in rapid process of multiplication the whole germinal zone is filled. This zone lies only in the principal hydranths, commencing a little below their necks and extending a shorter or further distance down the stem, but as a rule not further than the second lateral hydranth (*Kzo*, Fig. 3). Within this zone the production of new ovicells is almost entirely restricted to its uppermost region. As the principal hydranth grows, the germinal zone, which maintains a constant length, rises with it, and as soon as it rises above the point of junction of any lateral hydranth, this hydranth is cut off from any further supply of ovicells. The ovicells never occur in the endoderm within the germinal zone, but are only found in that layer within the hydranth and gonocope. This is because of the remarkable migrations which the cells perform, which take place in perfectly definite directions at definite times. The cells remain in their place of origin, the ectoderm of the germinal zone, until a new lateral hydranth bud begins to be formed, and into this they migrate through the ectoderm, not at once, but as soon as the hydranth has attained a well defined stem. They wait here in the ectoderm, growing considerably, until they have attained a certain size, and then bore their way into the endoderm, nearly all the cells in each lateral hydrocope effecting the penetration of the basement membrane simultaneously, just at the time when a blastostyle bud commences to form. The cells hold on to the basement membrane on its inner face by one end, and stretch forwards the other in the direction of the position of the future blastostyle, and become remarkably elongate, their free ends being drawn out into long slender filaments amongst the endoderm cells. As soon as a hollow is formed in the blastostyle bud they creep in, still clinging to the basement membrane and always to its endodermal face. As the hollow enlarges, more and more creep in, and the bud takes on a pear shape. As the gonophores are budded out from the blastostyle the cells pass into the endoderm of these, then almost simultaneously bore through the basement membrane again, and reach the ectoderm layer of the sporophores, their final ripening place. The ovicells never reach maturity on the hydranths in which they originate, but always in the blastostyle of a lateral hydranth.

In the male stocks of *Eudendrium racemosum* the place of origin of the germinal cells is the ectoderm of the region of gemmation of the lateral hydranths. Thence they migrate by the endoderm into the sporophores, and then like the ovicells bore their way out into their ripening place, the ectoderm of the sporophores.

In the other species of Eudendrium examined, *E. capillare*, the place of first appearance of both male and female germinal cells is in the endoderm.

The results obtained as to the history of the generative elements in the various species examined are given in a concise tabular form under a series of headings, the importance and distinctness of which will now be recognised. The case of Podocoryne is taken as an example. The German terms are not easy to find English equivalents for.

Podocoryne carnea

Keimstätte. Germinal place. (Layer in which the earliest appearance of the germinal cells can be detected.)	Male germinal cells: the ectoderm. Female germinal cells: the endoderm.
Keimzone Germinal zone. (Region of the colony where these cells are earliest detected)	In male stocks: the manubrium of the Medusa buds. In female stocks: the endoderm sac of the gonophore bud.
Abkunft. Actual origin of the most primitive germinal cells, (in very many cases a matter of inference only).	Male germinal cells: young ectoderm cells. Female germinal cells: probably ectoderm cells which have migrated into the endoderm.
Ripening place.	The ectoderm of the manubrium of free-swimming Medusæ.
Migrations.	The male cells none. The female cells out of the primary endoderm sac of the gonophore bud into the spadix and thence into the ectoderm of the manubrium.

The facts with regard to all the investigated species, when thus placed in a tabular form, appear at first sight so varied and complicated as to defy all reduction to uniform law. The germinal cells appear to be developed sometimes here, sometimes there, without rule of any kind and without definite relation to the germ layers. A most remarkable fact lies in the circumstance that the greatest differences in these matters occur in closely allied genera and even species. But, since this can occur without affecting the general evidences of these relationships, "the variations must depend on such differences as can occur amongst nearly related forms." And in this circumstance really lies in Prof. Weismann's opinion the key to the whole matter. By careful use of the comparative method, he has arrived at the conclusion that the differences in the position of the place of first appearance of the germs depend on a "phylogenetic shifting" of this position, and have ensued *pari passu* with the degeneration of the primitive free medusæ unto sessile brood sacs. The advantage gained by the animal in the shifting which has brought this about, has lain in the earlier ripening of the gonad elements.

In accordance with a widely accepted view, the sessile gonophores of all the attached hydromedusæ except hydra, are probably to be regarded as degenerated medusæ. In the ancestral medusæ the gonad elements of both kinds originated in the ectoderm of the manubrium, and ripened there as they do now in six out of seven Tubularine genera bearing medusæ examined by the author, viz. Dendroclava, Bougainvillia, Perigonimus, Cladonema, Corymorpha, Syncoryne. Both the origination and ripening of the germinal cells occurred during the free life of the medusæ. Certain causes rendered the free medusa stage disadvantageous, and in many instances the gonophores in consequence became sessile, whilst the sexual elements originated and ripened in them at an earlier stage. At first the elements retained the same place of origin as in the free medusæ, a condition which survives in the medusoid gonophores of the existing Cladocoryne. But it became advantageous that the elements should not wait for their formation by cell division and for their gradual maturation until the process of construction of the gonophores by budding had been completed, and thus the formation of the ovicells became shifted, and appeared in an earlier stage. What may be regarded as a first stage in this process is represented in Pennaria and Tubularia, in which the germinal cells of both sexes first appear in the endocodon (see Fig. 1) of the gonophore bud, being carried afterwards, as development proceeds, to the original ripening place, the manubrium. As a further stage in the process, the primitively ectodermal germinal cells migrated into the endoderm, and here we find them making their first appearance in all the Tubularinæ bearing medusæ or medusoid gonophores, in which they do not originate in the ectoderm of the manubrium or in the endocodon. Most important is the fact that in Podocoryne and Clava, and other forms, the male elements have a different place of first appearance from the female. In Podocoryne the male germinal cells arise in the ancestral place, the ectoderm of the manubrium; the female, however, first appear in the endoderm of the medusa bud. In Clava the male elements originate in the endocodon; in the female they are first detected in the endoderm of the gonophore stem.

Here the phylogenetic shifting of the place of first differentiation of the germinal cells has operated only in one sex or in one more than the other. In all such cases it is the place of first differentiation of the female elements which has undergone further shifting than that of the male, apparently because, under similar circumstances, owing to their more minute subdivision, spermaries become more easily and rapidly ripened than ovaries. In the case of *Eudendrium racemosum*, already described, three further stages of the shifting back of the place of origin of the germinal cells appear to have been undergone by the female stocks beyond those evidenced in Podocoryne.

In some forms, as in Cordylophora already described, the entire long migration takes place entirely in the ectoderm, and it is plain that the shifting of the place of origin of the germinal cells backwards from the gonophores has taken in different forms two different lines of progress, one into the endoderm, the other through the ectoderm only. It is a remarkable fact that in no real medusa is the place of first appearance of the germinal cells shifted further back than at most to the endoderm of the gonophore. The difference of position of the generative elements in the medusæ of the Campanularinæ is regarded by the author as secondary, derived from a primitive disposition, as in the Anthomedusæ, by phyletic shifting from the manubrium to the radial canals, evidence in proof of which is adduced.

A most intensely interesting section is that devoted to the subject of the migration of the germinal cells. These cells seem to be guided in their movements by an extraordinary instinct. Every ovicell on setting out for its travels appears to have before it a definite route to a particular gonophore, and to follow it with certainty; and, further, to be able to distinguish a young hydranth bud from a young blastostyle bud, never entering the one in error for the other. The migrations may be compared to those of certain birds the young of which are believed by some ornithologists to find their way to their distant home without the aid of any old birds who have already made the journey to guide them. The author suggests that it must be the outcome of an excessively fine sense of minute differences of pressure which enables the ovicells of Podocoryne, after they have bored their way into the ectoderm, to arrange themselves in four longitudinal rows in the interradii of the manubrium, instead of forming an even zone round it. No doubt, as he points out, the same laws are at work here which determine the size, shape, number, and sequence of the cells in every organism; but this free mobility of these germinal cells in the Hydroida, with their definite line of march and goal, is a new factor, to which there seems to be no parallel known in other groups, although migrating cells pursuing comparatively indefinite courses are known in most Metazoa. As having a nearer resemblance to these movements are cited those of the mesoblast cells which are set free from the blastophore of the gastrula larva of Echinoderms, and which arrange themselves in regular order on the inner surfaces of its cavity. That there is no absolute difference between these curious tissue-building migrations and ordinary growth follows from the evident fact that they have arisen phylogenetically out of the formation of organs by ordinary process of growth.

The question of the immediate origin of the primitive germinal cells of the Hydroids is discussed in a most able summary chapter of the utmost interest, but which it is impossible to do justice to here. With regard to the relations of the elements to the two layers, the conclusion is that in all the Hydromedusæ, including the Siphonophora, the actual origin of the primitive germinal cells is from ectoderm cells. In all cases in which the first traces of the germinal cells can only be detected in the endoderm, the parent primitive germinal cells have migrated out of the ectoderm. This position is supported by two lines of argument, the one drawn from the comparison of the various stages in the shifting of the place of origin of the germinal cells exhibited in the various species of Hydromedusæ, and especially in the two sexes of the same species, which points clearly to the original and essential source of both sexual elements having lain in the ectoderm, as is still the case in the primitive, hermaphrodite, freshwater Hydra; whilst the other dwells on the circumstance that in all Hydroids in which the first appearance of the germinal cells takes place in the endoderm, a satisfactory proof of the endodermal origin of these cannot be brought forward. Where they originate in the ectoderm their identity with young ectoderm cells is obvious. When found in the endoderm, at the bases of the peculiar flagellate cells composing this layer, they have a similar appearance to the primitive germinal cells found in the ectoderm, but no connection of gradation between them and the endoderm cells can be detected, nor any subdivision of the endoderm cells tending to their production.

Having arrived at the above conclusion, the author is led to believe, as already mentioned, that the division of the Cœlenterata into Endocarpæ and Ectocarpæ introduced by the brothers Hertwig may very probably still hold good, the Hydromedusæ, with the Siphonophora and Ctenophora, being sprung from a separate phylum of the primitive Cœlenterates from that comprising the Anthozoa and Scyphomedusæ.

The work closes with a reference to the question of the alternation of generations in the Hydromedusæ. Now that the cœnosarcal origin of the germinal cells is proved in so many instances, can the gonophores or medusæ, the sexual cells of which are formed in the cœnosarc of the hydranth or stem before they themselves are begun to be developed, be regarded as sexual individuals? It is obvious that it would lead only to confusion if the old way of regarding the matter was upset. The past history of the gonophores must be taken into account, and the fact that the sexual elements, though now developed at a greater or less distance in many species, formerly undoubtedly originated within the gonophores. If an opposite view were adopted, the absurd difficulty would arise that the male gonophores in some species would have to be taken as sexual individuals and the females in the same species as not.

The author's discovery of the gradual phylogenitic shifting of the place of origin of the sexual elements in Hydromedusæ seems, as he points out, to throw most happy light on the vexed controversy between Brooks and Salensky as to the alternation of generations in the Salpæ. The ovarium in the stolon of the solitary Salpa discovered by Brooks doubtless belonged originally to the sexual chain Salpæ and has become shifted in order to hasten its maturation into the stolon of the nurse, which is no more to be regarded as sexual because of its preparing an ovary for the buds than are the principal hydranths of *Eudendrium racemosum* to be regarded as such because they supply the ovicells to the gonophores borne by the blastostyles. As in so many of the Hydromedusæ, the male elements of the sexual individuals have undergone no corresponding shifting. The discrepancies between the results of the two observers probably depend on the circumstance that the process of phylogenetic shifting has attained, as in Hydromedusæ, different stages of development in the various species. The mode of reproduction of the Salpæ is still to be regarded as a case of alternation of generation, even should Salensky's well founded suspicion that the chain Salpæ are themselves able to produce a second ovary after the first has been used up prove invalid.

The remarkable differences in the development of the germinal cells in nearly allied Hydromedusæ seem to be paralleled to some extent by the extraordinary condition in the early embryology of the Salpæ discovered by Salensky,[1] where the differences occurring in the different species are so great and important that, as he writes, "they hardly bear comparison with one another." In all Salpæ the early segmentation of the ovum takes place as usual, but then "gonoblasts,' cells derived from the epithelium of the egg-follicle, not sexually fertilised elements, suppress the blastomeres, which atrophy whilst the entire embryo is formed from the gonoblasts with or without other unfertilised matter. Salensky calls this extraordinary process, which is without parallel in the rest of the animal kingdom, "follicular budding."

Possibly some of the curious differences as to the extent to which the gonoblasts and parts of the ovary and oviduct enter into the formation of the embryo in Salpæ (Gymnogonæ and Thecogonæ) may be hereafter explained on some such principle as that of Prof. Weismann of "phylogenetic shifting."

H. N. MOSELEY

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Public Orator (Mr. J. E. Sandys) made the following address to the Senate in presenting Mr. Andrew Graham, First Assistant to Prof. Adams at the Observatory, for the complete degree of M.A. *honoris causâ*. Mr. Graham discovered the ninth minor planet *Metis*, a fact cleverly turned to account by the Orator:—

"Dignissime domine, Domine Procancellarie et tota Academia:

"Quam invidenda nobis illorum vita est, qui a rerum terrestrium strepitu remoti, templum quoddam observando cælo dedicatum incolunt, ubi noctibus serenis tot lucidorum orbium ortus obitusque contemplantur, tot stellarum immotarum stationes perpetuas accuratissime definiunt, tot siderum errantium cursus prius ignotos admirabili quadam divinatione augurantur. Consentaneum nimirum est eum, cui primo quondam Oceani filia, Metis, inter sidera affulserat, tot annos in rure illo suburbano cum Neptuni inventore nostro celeberrimo feliciter esse consociatum. Iuvat certe tanti viri adiutorem fidelissimum hodie civitate nostra donare, virum et linguarum recentiorum et studiorum mathematicorum perquam peritum, neque in numeris tantum computandis sollertissimum, sed in sideribus quoque observandis perspicacissimum. Ipse rerum omnium Fabricator, cetera quidem animalia terram prona spectare passus,

> 'os homini sublime dedit cælumque tueri,
> iussit et erectos ad sidera tollere vultus;'

quanto igitur honore illi digni sunt qui, qua in re ceteris animantibus homines præstant, in ea hominibus ipsis tam præclare antecellunt.

"Vobis præsento virum et de scientia astronomica et de Academia nostra optime meritum, Andream Graham."

SOCIETIES AND ACADEMIES

LONDON

Geological Society, November 7.—J. W. Hulke, F.R.S., president, in the chair.—James Diggle. Charles Anderson Ferrier, and Prof. W. Stephens were elected Fellows of the Society.—The following communications were read:—On the geology of the South Devon coast from Tor Cross to Hope Cove, by Prof. T. G. Bonney, F.R.S., Sec.G.S. The author, after a brief reference to the literature of the subject, stated that the chief petrographical problem presented by this district was whether it afforded an example of a gradual transition from slaty to foliated rocks, or whether the two groups were perfectly distinct. He described the coast from Tor Cross round by the Start Point to Prawle Point, and thence for some distance up the estuary leading to Kingsbridge. Commencing again to the north of Salcombe, on the other shore of this inlet, he described the coast round by the Bolt Head and Bolt Tail to Hope Cove. These rocks, admittedly metamorphic, consist of a rather thick mass of a dark mica-schist and of a somewhat variable chloritic schist, which also contains a good deal of epidote. In the lower part of this are some bands of a mica-schist not materially different from the upper mass. It is possible that there are two thick masses of mica-schist, one above and one below the chloritic schist; but, for reasons given, he inclined to the view that there was only one important mass, repeated by very sharp foldings. The junction between the admittedly metamorphic group and the slaty series at Hope Cove, as well as that north of Salcombe, is clearly a fault, and the rocks on either side of it differ materially. Between the Start and Tor Cross the author believes there is also a fault, running down a valley, and so concealed. On the north side of this the rocks, though greatly contorted and exhibiting such alterations as are usual in greatly compressed rocks, cannot properly be called foliated, while on the south side all are foliated. This division he places near Hallsands, about half a mile to the south of where it is laid down on the geological map. As a further proof of the distinctness of the two series, the author pointed out that there were clear indications that the foliated series had undergone great crumpling and folding after the process of foliation had been completed. Hence that it was long anterior to the great earth-movements which had affected the Palæozoic rocks of South Devon. He stated that the nature of these disturbances suggested that this district of South Devon had formed the flank of a mountain-range of some elevation, which had lain to the south. Of the foundations of this we may see traces in the crystalline gneisses of the Eddystone and of the Channel Islands, besides possibly the older rocks of South Cornwall and of Brittany. He also called attention to some very remarkable structures in the slaty series near Tor Cross, which appeared to him to throw light upon some of the structures observed at times in gneisses and other foliated rocks.—Notes on Brocchi's collection of Subapennine shells, by J. Gwyn Jeffreys, F.R.S. In this paper the author gave the results of an examination of the collection of fossil shells from the Subapennine Pliocene described by Brocchi in his "Conchiologia fossile Subapennina," and now preserved in the Museo Civico at Milan. The author cited fifty-five of Brocchi's species, upon most of which the collection furnished more or less interesting information. In conclusion he remarked upon the importance of identifying Brocchi's species with forms still living in the neighbouring seas, and also upon the difficulty of distinguishing between the Upper, Middle, and Lower Pliocene in Italy. From his examination of Italian Pliocene shells he concluded that the deposits containing them were for the most part formed in comparatively shallow water, probably not more than fifty fathoms in depth, a remark which also applies to the Italian Miocene; and that in the case of species still existing no difference can be recognised between Pliocene and recent specimens.—British Cretaceous Nuculidæ, by John Starkie Gardner, F.G.S. The author commenced by discussing the question whether the Nuculidæ should be separated as a family from the Arcidæ, and stated that species of *Leda* and *Nucula* exist and sometimes abound in the marine Cretaceous deposits, with the exception of the White and the Red Chalk, from which, however, he thought that the shells may have been dissolved out. He also referred to the probable derivation of the species from preexisting forms, and discussed the question of how far the relationships thus established could be expressed in the nomenclature of the species, his researches upon the Nuculidæ leading him in some cases to suggest a trinomial nomenclature. The probable lines of descent of the shells described in the present paper were also discussed at some length.

Anthropological Institute, November 13.—Prof. Flower, F.R.S., president, in the chair.—The election of the following new members was announced:—Dr. G. B. Barron, Prof. D. J. Cunningham, H. O. Forbes, J. S. Hunt, Capt. E. C. Johnson, R. Morton Middleton, jun., Capt. C. A. Moloney, S. B. J. Skertchley Joseph Smith, jun., and Dr. Johnson Symington.—Mr. J. E. Price exhibited a selection of objects from ancient grave mounds in Peru.—Dr. Garson exhibited two iron lamps that he had procured from the Orkney Islands for the Oxford University Museum. They were very similar to the lamps of the Esquimaux described by Dr. E. B. Tylor in his paper read before the Institute at the end of last session, and each consists of two flat receptacles prolonged into a spout-like depression on the anterior portion.—Prof. Flower exhibited the skull of a young chimpanzee (*Troglodytes niger*) which had been sent to him from Lado in the Soudan, by Dr. Emin Bey. It was the subject of acrocephalic deformity, associated with complete synostosis of the coronal suture, and partial obliteration of the sagittal suture, both of which are normally open long after the age to which this individual had attained.—The Director read a paper by Mr. Edward Palmer on some Australian tribes.

Zoological Society, November 20.—Prof. W. H. Flower, F.R.S., president, in the chair.—A letter was read from Mr. G. B. Sowerby, jun., in which he proposed to change the name of *Thracia jacksonensis*, given in his paper "On New Shells," read in January, 1883, to *Thracia brazieri*.—A letter was read from Mr. W. H. Ravenscroft, of Colombo, Ceylon, describing the effectual mode in which a female Axis Deer in confinement concealed its young one from observation.—The Secretary exhibited, on the part of Major C. H. T. Marshall, F.Z.S., a specimen of a new Impeyan Pheasant from Chumba, N.W. India, which Major Marshall proposed to name *Lophophorus chumbanus*, and some other birds from the same district.—Mr. H. Seebohm, F.Z.S., exhibited and made remarks on a new Owl from Japan, which he proposed to call *Bubo blakistoni*, after Capt. Blakiston, its discoverer.—Mr. H. E. Dresser, F.Z.S., exhibited and made remarks on some Ringed Pheasants from Corea.—Prof. Bell, F.Z.S., exhibited and made remarks upon some Australian Crinoids infested by a large number of Myzostomata.—Prof. Flower read a paper on the characters and divisions of the family Delphinidæ, in which the following generic divisions were admitted and defined:—*Monodon*, *Delphinapterus*, *Phocæna*, *Neomeris*, *Cephalorhynchus*, *Orca*, *Or-*

Pseudorca, *Globicephalus*, *Grampus*, *Feresia*, *Lagenorhynchus*, *Delphinus*, *Tursiops*, *Clymenia*, *Steno*, and *Sotalia*. Critical remarks were added upon the characters and synonymy of the best-known species of each.—Prof. Flower also gave an account of a specimen of Rudolphi's Rorqual, *Balænoptera borealis*, Lesson (= *Sibbaldius laticeps*, Gray), lately captured in the River Crouch, Essex, being the first well-authenticated example of this species met with in British waters.—A communication was read from Dr. M. Watson, F.Z.S., containing additional observations on the structure of the female organs of the Indian Elephant (*Elephas indicus*).—A communication was read from Mr. F. Moore, F.Z.S., containing the descriptions of some new Asiatic Diurnal Lepidoptera.—A communication was read from Mr. R. Trimen, F.R.S., in which he gave a description of a remarkable semi-melanoid variety of the Leopard (*Felis pardus*) in the Albany Museum, Grahamstown, which had been obtained in the east of the Cape Colony.—A communication was read from the Count H. von Berlepsch and Mr. L. Taczanowski, in which an account was given of an extensive collection of birds made by MM. Stolzmann and Siemiradzki in Western Ecuador.

EDINBURGH

Royal Physical Society, November 21.—The first meeting of the 113th session was held in the Institution Rooms, St. Andrew Square, Dr. Ramsay H. Traquair, F.R.SS. London and Edinburgh, president, in the chair.—A nest of the reed-warbler, found near Combe Abbey, Warwickshire, was exhibited to the Society by Dr. Herbert.—The opening address of the session was then delivered by Dr. Archibald Geikie, F.R.SS. London and Edinburgh, Director-General of the Geological Survey of Great Britain and Ireland on "The Relation between Geology and Palæontology."

SYDNEY

Linnean Society of New South Wales, September 26.—Dr. James C. Cox, F.L.S., in the chair.—The following papers were read:—On a very dolichocephalic skull of an Australian aboriginal, by Baron N. de Miklouho Maclay. The cephalic index of this skull, which was found in the interior of Queensland, was only 58·9, calculated on the ophrio-occipital length, and 58·3, calculated by the glabello-occipital length, an index lower probably than that of any skull hitherto described. The skull was not a deformed one in the ordinary sense, but was a fair example of the so-called roof-shaped type of cranium.—On a fossil humerus, by Mr. C. W. De Vis.—Notices of some undescribed species of Coleoptera from the Brisbane Museum, by William Macleay, F.L.S. The species described are a few unnamed Coleoptera occurring in a large collection sent by Mr. De Vis to the author for identification. Their names are:—*Pamborus viridiaureus*, *Catascopus laticollis*, *Eutoma ponctipenne*, *Carenum terræ-reginæ*, *C. ianthinum*, *C. De Visii*, *C. pusillum*, *Tibarisus robustus*, *Pœcilus lævis*, *Diphucephala hirtipennis*, *D. cœrulea*, *D. latipennis*, and *Liparetrus convexiusculus*.

PARIS

Academy of Sciences, November 19.—M. Blanchard, president, in the chair.—Remarks on the recent volcanic disturbances in Sunda Strait; mineralogical analysis of the ashes collected, by M. Daubrée. From the examination of these ashes, which fell at Batavia on August 27, the author considers it highly probable that the surface waters penetrating deeply into the underground cavities, and there becoming superheated, form the chief agency in such volcanic eruptions as those of Krakatoa and Ischia.—On the velocities acquired in the interior of a vessel by the various elements of a fluid during its discharge through a lower orifice (continued), by MM. de Saint-Venant and Flamant.—On the process of purple dyeing amongst the ancients according to a fragment attributed to Democritus of Abdera, by M. Berthelot.—On the production of extremely low temperatures by means of continuous apparatus, by M. Cailletet.—Report on the French expedition to Cape Horn, by M. Martial. The expedition, undertaken mainly to observe the transit of Venus, embarked on board *La Romanche* at Cherbourg on July 17, and reached its destination on September 6. Three contacts were observed under favourable conditions by M. Courcelle-Seneuil. A great part of Tierra del Fuego was visited, numerous dredgings were made at various points, and rich collections, especially botanical and ethnological, were brought back These included living specimens of most of the Fuegian flora, two native canoes with their full equipment, a complete hut with all the utensils, arms, and other objects in use amongst the aborigines. A cairn twenty feet high was erected in Orange Bay to commemorate the French expedition to Cape Horn.—On the transformations of which certain equations of the second order are susceptible, by M. R. Liouville.—On the electrochemical energy of light, by M. F. Griveaux.—Observations of the Pons-Brooks comet made at the Paris Observatory (equatorial of the west tower), by M. G. Bigourdan.—Observations of the same comet and of the planet 234 made at the Marseilles Observatory, by M. Coggia. — Photometric observation of an eclipse of the first satellite of Jupiter, by M. A. Obrecht. — Remarks on a formula of Tisserand connected with celestial mechanics, by M. R. Radau. — On the resisting power of a ring, by M. J. Boussinesq.—On the curve-lines of wave surfaces, by M. G. Darboux.—Application of a proposition in mechanics to a problem connected with the figure of the earth, by M. E. Brassinne.—Note on the action of carbonic acid on saccharine dissolutions more or less charged with lime, by M. D. Loiseau.—On a new kind of ureometer (one illustration), by M. W. H. Greene.—Experiments on the passage of charbon bacteridæ into the milk of animals affected by charbon, by MM. J. Chambrelent and A. Moussous.—On the embryogeny of *Sacculina carcini*, an endoparasitic crustacean of the order of Kentrogonides, third note, by M. Yves Delage. In this highly important contribution to the study of parasitic entomology the author proposes to constitute a new order of Kentrogonides, distinct from, but allied to, that of the Cirrhipedes.—Development of the Stylorhynchus, by M. A. Schneider.—On the genus Ptychogaster, Pomel, a fossil Chelonian found associated with the remains of crocodiles in the Saint-Gérand-le-Puy formations, by M. L. THE GEOLOGY OF THE LIBYAN DESERT

Beiträge zur Geologie und Palæontologie der Libyschen Wüste und der angrenzenden Gebiete von Ægypten, unter Mitwirking mehrerer Fachgenossen, herausgegeben von Karl A. Zittel. I Theil und II Abtheilung, 1 Heft. (Contributions to the Geology and Palæontology of the Libyan Desert and of the Neighbouring Districts of Egypt. By Karl A. Zittel, with the assistance of several scientific men. Part I. and Part II., Section 1.) (Cassel: Fischer, 1883.)

IN NATURE, vol. xxii. p. 587, there appeared a notice of the anniversary address for that year to the Academy of Natural Sciences in Munich delivered by Prof. Karl A. Zittel, the well-known Professor of Geology and Palæontology at the Munich University. The address contained a preliminary sketch of the work, the complete account of which occupies the quarto volume and portion of a second volume now before us.

In the winter of 1873-74 a scientific expedition under the leadership of Gerhard Rohlfs was despatched with aid from the late Khedive of Egypt, Ismail Pacha, to explore the Libyan desert or north-eastern portion of the Sahara. The scientific results of this expedition are now being published in a series of separate volumes, of which the Geology and Palæontology will form two. The first of these lies before us, the second is as yet incomplete, and only one section containing a description of the Eocene Echinoidea, by P. de Loriol, has hitherto appeared. The first volume comprises the geological description of the country by Prof. Zittel himself, an account of the fossil wood from the Nubian sandstone and from the well-known "fossil forest" near Cairo (Cretaceous), by Dr. A. Schenk; of the Miocene fauna of Egypt and the Libyan desert, by Dr. Th. Fuchs; of the Tertiary (Upper Eocene or Oligocene) fossils from the western island in the lake of Birket-el-Qurûn (about fifty miles south-west of Cairo), by Prof. Karl Meyer-Eymar; of the Foraminifera (the Nummulites excluded) from the Eocene beds of the Libyan desert and Egypt, by Conrad Schwager; a monograph of the Nummulites from the same areas, by the late Dr. Phil. de la Harpe; and a description of the Eocene corals, by Magister E. Pratz. These palæozoic descriptions are illustrated by thirty-six plates.

The remaining portions of the second volume will include an account of the Eocene Mollusca, by Prof. Meyer-Eymar; of the Cretaceous fauna, chiefly by Prof. Zittel himself; and of a few other subjects. Amongst the contributors, besides those already enumerated, the names of Prof. Beyrich, the Marquis de Saporta, Prof. Haushofer, and Prof. Zirkel are mentioned in the preface to the first volume.

An array of scientific names like the above, chosen from amongst the most eminent specialists of Germany, Switzerland, and France, proves that this is a work of more than ordinary geological importance. The principal author and editor, Prof. Zittel, is both a good geologist and a good palæontologist, a much rarer combination than is usually supposed.

On the geological map in the first volume an area occupying rather more than 5° of latitude (25° to 30° N.) and above 8° of longitude (about 25° 30′ to 33° 40′ E.) is coloured. This country includes the Nile valley from Cairo to Edfu (the geology of the valley itself is shown as far south as Assuan), and extends eastwards to the shores of the Red Sea, and westward far into the great desert tract of Northern Africa. The whole area coloured geologically may be roughly estimated at between 150,000 and 160,000 English square miles.

It will easily be understood that the mapping is of a very rough description, a geological sketch in fact, but in desert countries, owing to the want of vegetation to conceal the rocks, and to the clearness of the atmosphere, it is remarkable with what accuracy geological formations can be traced by the eye to great distances. A considerable proportion of the area is coloured from the observations of other travellers, and especially of Schweinfurth. The routes of the expedition under Rohlfs and of other travellers are marked on the map, and show how much of the area has actually been examined.

Among the numerous points of interest presented by the volume it is difficult to select any one as superior to the others. In the former notice in NATURE the general characters of the geological systems observed (Cretaceous, Eocene, Miocene, and the so-called Quaternary and recent) were briefly described. To enter at any length into a notice of the palæontology would take too long. At the present time when the writings of F. von Richthofen and others have called especial attention to the subaërial or Eolian formations of the latest geological times and the present day, the description of the surface phenomena presented by the desert tracts of the Sahara, coming from so keen an observer as Prof. Zittel, are well worthy of attention, and a few remarks upon them may prove interesting.

The geological portion of the work is divided into two chapters: the first, containing forty-two pages, being devoted to the Sahara as a whole; the second to the geology of the Libyan desert and Egypt. In both of these chapters considerable space is devoted to the superficial characters of the desert. The surface of the Sahara is divided by Prof. Zittel, according to its characters, into four kinds:—(1) Plateau-desert or Hammâda, occupying the largest portion of the area, a level, hard, stony surface in general, without noteworthy elevations or depressions, but passing locally into (2) mountainous desert. The so-called (3) erosion-desert consists of depressions more or less occupied by salt-marsh. The last form of surface, the most remarkable and interesting of all, is the (4) sandy desert or Areg, composed of drift sand forming hills or downs (dunes).

Prof. Zittel shows, on what appears to be an overwhelming amount of evidence, that the popular idea of the Sahara having been the basin of a sea in Pleistocene times is without foundation. The greater part of the area has apparently been above water ever since the Cretaceous epoch; a comparatively small tract in the north-eastern portion was submerged beneath a Tertiary sea, whilst the only part that can have been under water in post-Tertiary times consists of a tract extending from the Nile delta to the oasis of Ammon, and to the so-called "Chotts" of Tunis, and even in this tract marine conditions in late geological times are doubtful. But Prof. Zittel considers that the climate must have been damper, the rainfall heavier, and freshwater denudation more active in Pleistocene days than now, to account for the erosion that has taken place, the abundance of fulgurites, and the present distribution of the fauna and flora, especially in such cases as the occurrence of Central African crocodiles in the marshes and streams of the completely isolated Ahaggar Mountains. Reasons are also given for believing that the Nile was formerly a larger river than it now is. It is probable that Prof. Zittel's views on some of these points will be contested, but it is impossible to deny that his arguments are admirably expressed and clearly reasoned out.

Some very interesting details are given about the desert sand, and a careful description of its arrangement in the form of sandhills. The sand of the Sahara is considered to have been largely derived from the decomposition of the so-called Nubian sandstone, the original matrix of the well-known silicified wood. In the Libyan desert there are some remarkable anomalies in the arrangement of the sandhills, and it is clear that they cannot have been entirely formed by accumulation through the agency of the prevailing wind as it exists at the present day. It may here be remarked that very similar observations were made, a few years since, upon the sand ridges of the Indian desert east of the Indus. Some of the sand ridges, both in Africa and India, attain an elevation of about 500 feet, and in both areas the largest appear to have undergone no change within the memory of man, although in places, in both continents, moving tracts of sand occasionally overwhelm cultivated land and buildings.

One mistake in the book deserves notice. In the comparative table of Upper Cretaceous and Eocene beds in Europe, Asia, North Africa, and North America the position assigned to some of the Tertiary stages of the Indian rocks requires correction. The lower Nari beds in especial were never supposed to be so old as Middle Eocene (Parisian), and they are now known to be in all probability true Oligocene. But trifling mistakes of this kind are to be expected: it is surprising that more should not have been observed.

W. T. B.

APPLIED MECHANICS

Applied Mechanics. By H. T. Bovey, M.A., Professor of Civil Engineering and Applied Mechanics, McGill University, Montreal, Fellow of Queen's College, Cambridge. Part I., pp. 190. Part II, pp. 150. (Montreal: J. Lovell and Son, 1883.)

THIS work appears to be designed as a college text-book for somewhat advanced students, who have already received good training in mathematics (as far as the elementary parts of the integral calculus) and theoretical mechanics.

Part I. treats of the strength of materials, dealing with longitudinal stress, the strength of beams and pillars, torsion, and the strength of hollow cylinders and spheres.

In Part II. we have chapters on frames, roofs, bridge-trusses, suspension bridges, arched ribs, and in conclusion one on "details of construction," which includes a discussion of the strength of rivets and other fastenings.

In his exposition of these subjects the author manifests a power of clear and precise statement; and the treatment of the more difficult problems of the first part is perhaps as profound as could be attained without a knowledge of the general theory of elasticity. The numerous illustrations serve sufficiently well in Part I., where they consist chiefly of diagrams; but in Part II. they are on too small a scale for the complicated structures illustrated: and in clearness of detail are far below the standard reached in recent English books on the same subjects. Analytical methods are preferred throughout; and generally speaking geometry is used merely to illustrate results previously obtained in a symbolical form. Thus graphical statics is quite subordinate in Part II.; stress diagrams are introduced, but there are not sufficient instructions in the text to enable a student, who has not studied the subject independently, to construct them for himself.

In the extended treatment of a parabolic rib of uniform stiffness (pp. 101-120) the author follows very closely the lines in Rankine's "Civil Engineering," with some further consideration of the additional terms depending on change of temperature.

There is no acknowledgment in regard to this and other parts of the work where Rankine's influence is clearly apparent. But as no preface is given to the present volume, perhaps other portions of the great subject of applied mechanics are in course of preparation by our author; and till the completion of his work he is postponing the statement of his obligations to those who have gone over the ground before.

We have referred to the apparent excess of symbolical reasoning: but none of this is due to the introduction of investigations better left to treatises on pure mathematics and theoretical mechanics.

Difficulties special to the subject of the work, such as the equations of the "neutral axis" (so-called) for all the different modes of loading and supporting a beam, the theorem of three moments, the moments of inertia of complicated forms of section, the deflection of struts, are however treated with the fullness of detail required by ordinary students.

Such investigations constitute the best feature of the book. The detailed application to problems such as occur in actual practice is but slightly touched on; perhaps for this we are to look to the "Examples," of which some few are worked out in the text; appended to the several chapters, moreover, are close upon 400 proposed for the exercise of the student.

These form a very important collection. A great number involve numerical results, and unfortunately the answers are not given; this greatly lessens their value for private students at any rate. Several examples are taken from existing structures, and are liberally furnished with diagrams in illustration of the data.

Many are new to text-books, and the author has evidently taken great pains in collecting and arranging them.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Meteors

HERE, November has generally been unpropitious for astronomical observations. However, during favourable intervals I have seen many brilliant meteors; from twenty to thirty on an average every night. They were principally seen with the face to the north, and glancing from shoulder to shoulder; but not a single Andromede did I see. I had the pleasure of seeing altogether about a score of Leonids before the 12th and after the 19th November. Leo Minorids and Arietids were plentiful, and a goodly number of Geminids were seen; but the richest field for meteors during the month was in the neighbourhood of the Plough. November 6, at 4.30 a.m., a large meteor passed from γ Ursæ Majoris right down to the horizon. From 4.35 to 5.15 three veritable Leonids proceeded from the Sickle; one dashed down to the right-hand, and another from the top of the Sickle to the left over the Lion's back. They were very large. November 10, at 8 p.m., a brilliant meteor started from a point nearly half way between Aldebaran and Saturn, and disappeared at a point down more than half way to the horizon. At 9.30 a very bright one appeared at a point about 1° above Castor and above Jupiter to the north. At 11.25 an exceedingly large and brilliant meteor burst out from ½° below Menkar (in the Whale), and went down at right angles to the very horizon, leaving a long, bright streak behind. November 11, a large one, at 0.15 a.m., dropped down to the horizon from θ Ursæ Majoris. At 0.55 a.m. a very large one proceeded from ½° to the right of α Lacertæ and disappeared at γ Cygni. November 18, at 1.40 a.m., a very large reddish meteor burst out from the top of Ursa Major's head, and passed right above Vega, and disappeared about 4° beyond it in a strange sparkling explosion. At 1.55 a.m. a very brilliant meteor dashed out about 2° above α Arietis, went through the Square of Pegasus, leaving a beautiful stream of blue fire behind, and lasting a few seconds. About 5.30 another large blue meteor passed from the centre of Leo's back through a point 4° above Denebola, and ended in a beautiful explosion 15° beyond. On the night of November 22 there was a fine display of (generally) large meteors from Taurus to Ursa Major; many of them proceeded from the Lion's Head. During the month a great number of meteors passed from some point in Scorpio, under Jupiter and Mars, right into the Lion's Head. They were all large and bright. During the last half of the month some fine displays of morning meteors were seen. At 4 a.m., November 29, I observed a very large and swift meteor. It blazed out from a point about 8° above Denebola, and dashed with great velocity up the heavens, passing 4° above δ Leonis and over the Lion's Head, and exploded about 5° beyond, leaving a stream of the most beautiful blue light in its wake that I ever witnessed. DONALD CAMERON

Mossvale, Paisley, December 3

As your columns frequently contain notices of meteors, I may mention that I observed one of unusual brilliancy last night (November 28) at 10.50. It appeared in the constellation Taurus, and, following the line of the ecliptic, disappeared about five to ten degrees above the eastern horizon. The meteor was visible for not less than fifteen seconds, had a brilliant train or cone of light of from two to three degrees in length, and outshone Jupiter, near which it passed. From the slow, angular movement of the meteor I feel certain that the train was not an optical impression, but a real luminous object. F.R.S.E.

Edinburgh, November 29

A FINE meteor was observed here by me at 10h. 38m. last night, Wednesday, November 28. Bursting into sight near λ Ursæ Majoris, it passed in a course almost parallel to, but about 2° north of, a line joining α, δ, ϵ, ζ, and η Ursæ Maj., its light expiring near λ Boötis. Length of path = 40°. No train was observed; the only variation of uniformity of light being at about half way of its passage, where it slightly paled for an instant and then as quickly recovered. Duration about four seconds. Brilliancy three or four times Venus at its brightest. Colour resembled that of magnesium light. W. WICKHAM

Radcliffe Observatory, Oxford, November 29

LAST night, about 10 30, I saw a magnificent bolide shoot across the sky in a northerly direction. It came from the middle star in Orion's belt, and disappeared at a point almost in a line with "the Pointers" in the Great Bear, and at a distance below the lower of the two stars almost equal to the distance between them. Its path was perceptibly arched, but not to any great extent, and, as far as I could judge, it was not parabolic. When the bolide first appeared, it seemed a mere luminous point moving with great rapidity, and without a tail. But about half way it suddenly grew large and brilliant, a tail shot out, and the path behind it remained luminous and distinct. I could compare the bolide at this point to nothing so much as to a red-hot cannon ball emitting sparks of fire. It was accompanied by no sound, and was gone in half a dozen seconds. During its passage the streets seemed to be lit up with the electric light. It was apparently so close that I should think a few miles would have made a very sensible difference in its apparent position in the heavens. J. B. OLDHAM

Stockport, November 29

LAST night at 11h 2m. I saw in the north-west, near the horizon, one of those slow-moving balls of fire, not so bright as an ordinary meteor, and leaving no train. This seemed the size of a cricket ball; but I have seen one the size of a cheese-plate. A few flashes of lightning occurred soon after. From the slowness of the motion the phenomenon seemed to be wholly atmospheric. It was in sight for about three or four seconds. It instantly suggested an incandescent vortex whorl; but I cannot say whether the appearance confirmed the idea or not, for I do not know how such a meteor would look. Its red light might be due to its proximity to the horizon, perhaps 8°. Hence there is no dependence to be placed upon my impression that the light was the result of friction rather than of electricity. I have seen probably a dozen in the course of my life, always in the west or north-west, and always about the same height from the horizon, but never annular. HENRY H. HIGGINS

Rainhill, December 4

"Anatomy for Artists"

MAY I add a few more words on the subject of Mr. Marshall's book, and in answer to his letter in NATURE? Mr. Marshall says the reasons that led him to adopt the plan of omitting reference letters to his illustrations of the bones "still remain sound." Turning to p. 30 of the book to learn those reasons, I find he says that "The numerous minute points which demand the attention of the anatomist and the surgeon necessitate such aids; but the art-student's mind should be left unincumbered by such unnecessary details."

I cannot see that this is a reason; I wanted references to what is described in the text—to the necessary, not the unnecessary details.

Secondly, Mr. Marshall says, "The pure form of the bones, represented on so small a scale, in black and white, would have been seriously marred by such references." If this be "sound," may there not be more and equally sound reasons for opposing it? I think there are; and if Mr. Marshall will turn to p. 136 of the book, I will try to show him how his plan works. The student reads there that "All the bones of the hand are visible in the skeleton, on its palmar aspect (Fig. 58), carpal, metacarpal, and phalangeal;" he turns to Fig. 58, but where is it? It is mentioned in a list of figures under *three* illustrations. He has to make up his mind which of the three is 58, recalls that it is the palmar aspect, and goes on. He has no clue, let Mr. Marshall observe, by which to know which are the carpal, metacarpal, and phalangeal portions of the hand for which he originally looked at the palmar aspect of it. He hopes he may come to that; and, reading on, finds that the eight carpal bones are "in the carpus;" but then, which *is* the carpus? He does not know, and is not told. Never mind, he thinks, he will find that out by the description of the single bones, and, beginning with the first-mentioned, he reads that the semi-lunar bone ". . . . occupies the centre of the first row, and is crescentic in shape." Looking again at the illustration, for "rows" he finds that the bones which seem to be arranged in rows are those which he may afterwards learn to be the metacarpals and phalanges. Supposing, however, that he guesses the carpus rightly, which of its bones is semi-lunar or crescentic in shape? I think if the picture were put before *any* ordinary observer, told to point out a crescentic bone, he would select the scaphoid. There is, thinks the student, still a clue left, for the semi-lunar "occupies the centre of the first row." But the first row contains *four* bones; at least he has read that "the eight bones are clustered together so as to form two groups," and he is not told that these groups are not the "rows" afterwards mentioned. He gives it up, and reads the other bones to learn them and find the semi-lunar by the exhaustive process. The guide he finds to the cuneiform bone is that it is "on the ulnar side of the semi-lunar," which he has perhaps failed to guess rightly, and articulates with certain other bones, which are to be afterwards described, and are unknown to him; and so on.

The mode of progression is like that I made once in Ireland, when on asking a peasant my way I was told to take the last turning before coming to the next milestone. There were a good many steps to retrace after finding the next milestone.

I have no doubt at all of the moral influence of Mr. Marshall's plan *if the student perseveres in using his book;* he will have exercised patience, attention, command of temper, and careful criticism of words, but I do not think his anatomical will equal his moral gain.

The process described above simply distracts the student's attention from the form of what he is studying. Would Mr. Marshall wish the Map of England taught in the same manner—no names or references given to the counties, and Hampshire to be recognised because it is in the last row and adjoins certain other counties, which in their turn adjoin it?

ART STUDENT

Barytes from Chirbury

I HAVE to thank Mr. Woodward for pointing out that the plane (412) has been established for barytes. It was first given by Helmhacker (*Denksch. der K. Akad. der Wiss. Wien.* vol. xxxii. 1872) as occurring on crystals from Svárov and Krušná hora in Bohemia, but is rejected by Schrauf as insufficiently determined. The distinguishing peculiarities of the Chirbury crystals are (1) the predominance of the plane E which does not truncate an edge as is the case in Carl Urba's crystals; (2) the frequent occurrence of ω and ξ; (3) the tendency of the face o to develop small faces on its edges which are inclined to o at angles near 3°. Such faces are Q and Y, and I have since determined a face A on the edge $o\mu$ with indices near (25.1.27).

British Museum, November 26 H. A. MIERS

THE ORIGIN OF CORAL REEFS[1]

II.

THE most detailed investigation of coral-reefs which has yet appeared has just been published by Prof. A. Agassiz.[2] This able naturalist is engaged in prosecuting a series of researches into the biological phenomena of the seas on the eastern side of the United States, under the auspices of the United States Coast Survey, and in the course of these explorations he has had occasion to devote himself to the detailed study of the coral-reefs of the Florida seas. For purposes of comparison he has likewise visited the reefs among the West Indian Islands, as well as those on the coast of Central America. His observations are thus the most exhaustive and methodical which have yet been published, and the deliberate conclusions to which he has come deserve the most attentive consideration. He traces the history of a coral-reef from its latest stages as dry land to its earliest beginnings, and even beyond these to the gradual evolution of the conditions requisite for the first starting of the reef. His familiarity with the nature of the bottom all over the area in question, and with the life so abundant in the tropical waters, gives him a peculiar advantage in this inquiry. The upheaval of recent coral-formations to considerable heights above the sea in various parts of the region enabled him to examine the inner structure and foundations of the reefs, and to obtain therefrom altogether new data for the solution of the problem. Following him in his induction we are led back to a comparatively recent geological period, when the site of the peninsula of Florida was gradually upraised into a long swell or ridge, having its axis in a general north and south direction, sinking gently towards the south, but prolonged under the sea as a submarine ridge. The date of this elevation is approximately fixed by the fact that the Vicksburg limestone was upraised by it, and this limestone is assigned to the Upper Eocene series. As a consequence of the elevation, a portion of the sea-bottom was brought well up into the waters of the Gulf Stream, which were probably shifted a little eastward.

No marine fauna yet explored equals in variety of forms or number of individuals that which peoples the waters of the Caribbean Sea and the Gulf of Mexico from the depth of 250 to about 1000 fathoms. This prolific life is traced by Prof. Agassiz to the copious food-supply carried by the warm tropical currents, combined with the food borne outwards from the sea-board of the continent. The corresponding abundant fauna found by the *Challenger* in the Japanese current may be regarded as its counterpart in the Pacific Ocean. Prof. Agassiz points also to the diminished richness of the fauna on the western side of the continents as being probably connected with the absence of those warm equatorial currents which bring such an abundant supply of food to the eastern shores. "No one," he remarks, "who has not dredged near the hundred-fathom line on the west coast of the great Florida Plateau can form any idea of the amount of animal life which can be sustained upon a small area, under suitable conditions of existence. It was no uncommon thing for us to bring up in the trawl or dredge large fragments of the modern limestone, now in process of formation, consisting of the dead carcasses of the very species now living on the top of this recent limestone." Mollusks, echinoderms, corals, alcyonids, annelids, crustacea, and the like, flourish in incredible abundance on the great submarine banks and plateaux, and cover them with a growing sheet of limestone, which spreads over many thousands of square miles and may be hundreds of feet in thickness. In these comparatively shallow waters, and with such a prodigiously prolific fauna which supplies constant additions to the calcareous deposit, the solvent action of the carbonic acid upon the dead calcareous organisms is no doubt reduced to a minimum, so that the growth of the limestone is probably more rapid than on almost any other portion of the sea-bottom.

From the charts we learn how extensively submar[illegible] banks are developed in the West Indian region in [illegible] track of the warm currents. East of the Mosquito Co[illegible] in Central America, one of these banks may be said [illegible] stretch completely across to Jamaica. Similar banks [illegible] off the Yucatan coast; likewise on the windward sid[illegible] the islands, where the ocean currents first reach them.

That these banks lie upon volcanic ridges and pe[illegible] can hardly be doubted, though we have no means of [illegible] ing what depth of recent limestone may have accumula[illegible] upon them. Among the islands, recent volcanic ma[illegible] rise high above sea-level, in Martinique reaching a he[illegible] of more than 4000 feet. And as usual in volcanic reg[illegible] there are numerous proofs of recent upheaval, such [illegible] the Basse Terre of Guadaloupe, the successive terrac[illegible] recent limestone in Barbadoes, and the upraised co[illegible] reefs of Cuba, which lie at a height of 1100 feet ab[illegible] sea-level.

The West Indian seas have long been famous for t[illegible] coral-reefs. Prof. Agassiz insists that the distributio[illegible] these reefs is determined by the direction of the f[illegible] bearing ocean currents. They flourish on the windward side of the islands and along the whole eastern coast of Honduras, Venezuela, and Yucatan. But on the leeward shores they do not exist at all. Cuba is fringed both on the north and south side with reefs, but the southern reefs, directly bathed by the Gulf Stream and exposed to the prevailing winds, are more flourishing than the northern reefs, which are to some extent cut off from the equatorial current by banks and islands.

---

[1] Continued from p. 110.

[2] "On the Tortugas and Florida Reefs." *Trans. Amer. Acad.* xi. (1883).

The depth at which corals will flourish in these seas has been found to be rather less than that which has been ascertained to be in general their downward limit elsewhere. Prof. Agassiz concludes that they do not thrive below a depth of six or seven fathoms in the Florida seas, though on the outer reef, directly exposed to the open currents and prevalent winds, they descend in scattered heads to about ten fathoms.

Each successive stage in the growth of an atoll seems to be laid open for study in the prolongation of the Florida reefs. The map of that region (Fig. 2) shows a remarkable broken line of islets and strips of land running parallel with the coast, first in a southerly direction, but gradually curving round until it takes a due westerly trend. This westward curve is attributed mainly to the influence of the strong counter-current which, with a width of ten to twenty miles, sweeps westward into the Gulf of Mexico along the left side of the Gulf Stream, and heaps up organic debris in its track. Florida is growing westward in the line of this current. Reef after reef is added to the land at the east end, while towards the west, new reefs successively begin on the bank, as its surface is gradually built up by the accumulation of organic debris

The last and youngest of the reefs marked on the maps and charts is the group known as the Tortugas. But immediately to the west of this group Prof. Agassiz has found a prominence on the submarine bank, on which corals have begun to grow. Large heads of Astræans and Madrepores have fixed themselves at a depth of from six to seven fathoms, and Gorgoniæ are found a little lower. This is the beginning of an atoll. The Tortugas, which present a further stage of development, consist of an elliptical, atoll-shaped reef, in three chief parts, whereof the largest forms a crescent, fronting to the east round the edge of the submarine bank, while the two other portions have grown south-westwards along the bank. Three channels between these portions allow powerful tidal currents to rush across the central chiefly submerged parts of the atoll. Seven islands have been formed at the higher parts of the reef by the accumulation and induration of calcareous debris tossed up on the reef by the waves. To the breakers and currents combined with the distribution and habits of growth of the reef-builders Prof. Agassiz entirely attributes the form and growth of the reef. The most important corals are the Madrepores, which flourish in extensive patches, two common species of *Porites* occurring in clusters over the shallow tracts of coarse sand, and *Mæandrina areolata*, growing between the marine lawns of *Thalassia*, with occasional patches of *Anadyomene*. Immense masses of nullipores and corallines grow on the tops of the dead branches of Madrepores which have been killed by exposure to the air during extreme low tides or when strong winds have blown the water off the flats. Large heads of Astræans and *Mæandrina* occur here and there towards the edge of the reef, which is occupied mainly by clusters of *Gorgoniæ*. The destruction of the reefs by the waves is very great, the sea being occasionally discoloured with the chalky sediment to a distance of from six to ten miles after a storm. Broken coral-heads, and branches, dead corallines, shells of mollusks, old serpulæ tubes, stalks of *Gorgoniæ*, and other organisms are thrown up in lines that consolidate into a low dyke, which in turn is pounded up and removed by the breakers. A prodigious quantity of calcareous-sediment is thus produced, much of which is swept into the interior of the reefs, where it accumulates in flats of sand and silt. It is only on the outer edges of the reef, where the scour of the sea is greatest, that the corals can flourish; elsewhere they are choked and buried under the deposit of calcareous sediment. Some of this sediment accumulates in steep submarine banks, like sand-dunes, which shift to and fro as winds and currents vary; though by the action of the carbonic acid of the sea-water they are apt to be cemented into solid slopes, some of which have an angle of as much as 33°. So great is the destructive and transporting influence of the sea under the combined or antagonistic working of tides, currents, and wind-waves, that the whole mass of the reef as well as the flats and shoals inside may be said to be in more or less active movement. Hence none of the

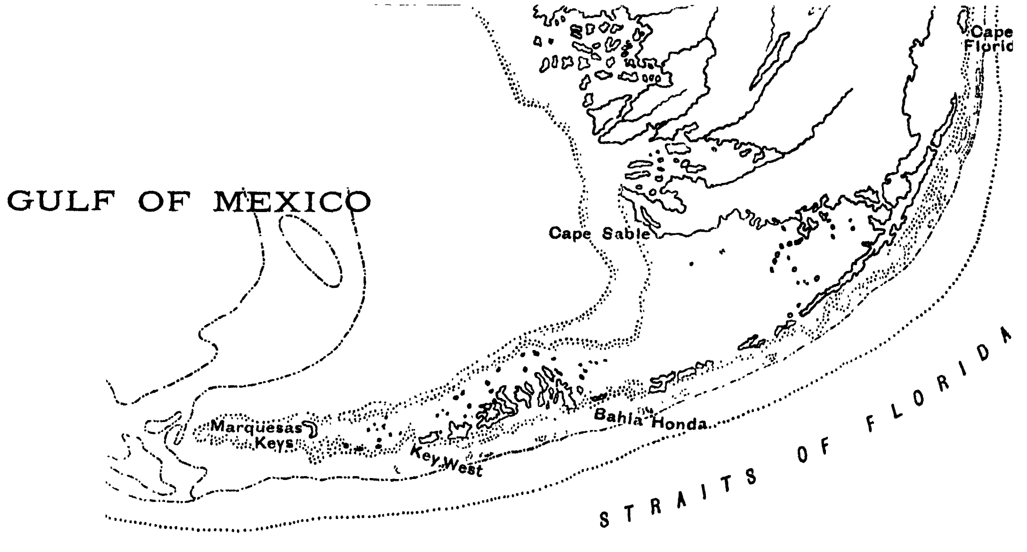

FIG. 2.—Map of the Florida Reef and Keys.

landmarks furnished by the islands can be relied upon for the location of buoys.

A still more perfect example of an atoll formed under similar conditions is that of Alacran on the opposite coast of Yucatan. Its eastern face is a great arc of about 20 miles, where, exposed to the open sea and easterly winds, the corals flourish vigorously. On the eastern or interior face of the western chord of the reef, however, the silt derived from the pounding of the breakers to the eastward has already killed the corals. The lagoon is occupied by detached coral-heads with lanes of deep water between them.[1]

To the east of the Tortugas, nearer the mainland of Florida, older stages of development among coral-reefs may be traced. By the westward drift of the calcareous sand and silt the lagoons have been converted into flats, and these in succession have been turned into more or less continuous dry land. There is no evidence of subsidence. The area seems to have remained stationary for a long period, or if there has been movement at all, it has been in an upward direction. Should the present condition of things be prolonged, there will be a further extension of the Florida coast-line. By the heaping up of the shells of dead organisms in the track of the counter current, the submarine bank will continue to be brought up within the depth at which reef-building corals can flourish. Successive clumps of reef-builders, springing up and growing outward, will build up atoll-shaped reefs. The abrading action of the waves upon these reefs will furnish detritus to be drifted into the lagoons and channels, which will eventually be silted up into dry land.

An interesting indication of the progress of these changes is furnished by the terrestrial flora and fauna of the reefs. The plants of the mainland are found likewise on the reefs, but become fewer in number as they are followed southward, until on the Tortugas,—the last addition to the dry land,—the flora consists of a few Bay-cedars, a hop-vine with a thick white flower, Bermuda grass, and a solitary mangrove tree. One of the species of land-shells common at Key West has found its way to the Tortugas. No terrestrial reptiles have yet reached that furthest atoll, though at Key West, less than 100 statute miles to the east, many of the frogs, toads, lizards, and snakes common to the southern mainland have already established themselves.

It will be observed that the conclusions arrived at by Prof. Agassiz from his own independent researches entirely confirm those previously announced by Mr. Murray. That two observers, who have enjoyed exceptional advantages in the investigation of this subject, should come to practical agreement must be admitted to be a strong argument in favour of the views which they have adopted.

Putting together all the data which have here been summarised, I think we are driven to admit that barrier reefs and atolls may be formed without subsidence of the sea-floor. Whether this has been the usual or only an exceptional manner of their origin is a question that will depend for its solution upon whether or not it can be shown that there are general phenomena which can only be explained by subsidence. Three such phenomena may be adduced: I am not aware of any others that deserve serious consideration.

1. One of the early difficulties which Darwin's explanation satisfactorily solved was the necessity for the existence of so many peaks, coming up from the depths of ocean just to the zone in which reef-building corals live. No cause was conceivable which should have so generally arrested the upward growth or upheaval of these submarine heights at the limit where coral-reefs might begin. And this difficulty has always been looked upon as furnishing one of the strongest arguments in favour of the theory of subsidence, for that theory completely removes it, by showing how, in a general submergence, peak after peak would sink, and come within the sphere of the operations of the reef-builders.

The difficulty is met in a totally different way by those who believe it to be more formidable in appearance than in reality. They contend that, while it must not be forgotten that many peaks do rise above the sea-level, and many submarine banks still fall far short of the coral-zone, two powerful causes conspire to bring submarine banks to a common uniformity of level at a short distance below the surface of the ocean. On the one hand, those portions of volcanic mountains that rise above the sea-level are worn down by the atmosphere and the waves, and unless otherwise preserved, must inevitably be reduced to the lower limit of wave-action, which is probably nearly coincident with the lower limit of reef-builders. On the other hand, submarine banks in tropical seas are built up towards the surface by the accumulation of the aggregated remains of plants and animals which live on the bottom or fall down to it from upper waters, and the magnitude of this upward growth is hardly yet adequately realised.

In balancing these opposite views, we must, I think, admit that subsidence is adequate to provide platforms for coral-reefs, but that these platforms could likewise be furnished by the two other processes just referred to. Subsidence has been invoked because no other solution of the problem seemed admissible. But as another solution has been found the argument in favour of subsidence has no longer the same force. The new solution, being based upon facts which are everywhere observable in the coral regions, appears to me to be more probable than the older one, which is only an inference resting on no positive proofs.

2. The precipitous descent of the outer face of the reefs to depths far below those at which corals can live is another difficulty which finds a ready explanation on the theory of subsidence. If it were true, as is popularly assumed, that a coral reef presents towards the ocean a vast perpendicular wall of limestone, entirely composed of solid coral, there could be no escape from the conclusion that subsidence must have occurred, to permit of such an aggregation of coral-rock. We learn, however, that much misconception exists on this subject. Some of the earlier accounts of coral-islands speak of "unfathomable" depths at a short distance seawards from the reefs; but more recent soundings afford no confirmation of these statements. Instead of being the summits of vast submarine pillars of limestone, atolls, as well as barrier-reefs, appear to be really planted on the tops of submarine peaks and ridges. The outer face of the reef is undoubtedly steep, in some places vertical. At Tahiti, for example, as shown in Fig. 2, the living face of coral may extend to a depth of 30 to 35 fathoms, beneath which huge detached blocks of coral are piled up and cemented together, forming a steep face, which descends to about 150 fathoms at a distance of 180 fathoms from the upper edge of the reef. The sea-bottom beyond that point is covered with coral sand and slopes at 25° to 30°, after which the angle lessens to 6°. By the abrading action of the breakers in tearing off blocks of coral, and strewing them down in steep talus-slopes, a platform is prepared on which the actually growing part of the reef can build outwards.

In Darwin's section of the Gambier Islands the thickness of the encircling reef is made to be about 2000 feet.[1] Prof. Dana by one estimate puts it at 1150, and by another at 1750 feet. He assumes that in general the thickness of solid coral must be considerable, though he admits that calculations based on the seaward continuation of the slope of the land are liable to error from many causes.[2] Even if we admit (what cannot be proved) that the calcareous mass of any coral-reef does attain a thickness of many hundred feet, it would not necessarily consist wholly of solid coral.[1] Prof. Agassiz has followed the growth of a reef upon a platform of calcareous organic debris, and he has found elevated coral-reefs which rest on such a platform. Mr. Murray's observations explain how a reef may grow outward on a talus of its own debris. There appears to be no reason, indeed, why a calcareous mass of almost indefinite thickness might not be formed without the aid of subsidence. Its upper zone might be directly due to coral growth, while the larger part of the mass might be composed of an aggregate of coral debris mixed with the remains of mollusks, echinoderms, and other calcareous organisms. So rapid is the destruction of organic structure through the solution and redeposit of carbonate of lime by infiltrating water, that a special and careful search might be required to determine the actual limits of the true reef and of its calcareous platform, and even such a search might not be successful.

[1] "Coral Reefs," 2nd edit. p. 65.

[2] "Corals and Coral Islands," 2nd English edit. (1875), p. 126.

After a full consideration of this second difficulty I feel compelled to admit that no valid argument in favour of subsidence can be based on the steepness of the seaward face of a reef and the thickness of the calcareous mass of the reef itself.

3. The depth of some lagoons and lagoon-channels furnishes probably the strongest argument in favour of Darwin's views. Occasionally a depth of forty fathoms is reached, and as this is beyond the depth at which reef-builders ordinarily live, it has been regarded as a proof that subsidence has taken place.

This third difficulty is thus met by the opponents of subsidence. We must remember, they say, that from the very conditions of their growth, patches of coral tend to assume an annular or atoll-like form, because the outer parts grow vigorously, while the central portions eventually die. Where the coral-patches coalesce and extend along a bank or shore, it is their outer or seaward faces that flourish. The inner parts, as they are more and more cut off from the food-supply, gradually die. While the outer face of the reef grows seaward, the inner margin is attacked partly by the solvent action of the carbonic acid of sea-water, partly by wind-waves, and the tidal scour sweeps away much fine detritus through gaps in this reef. In this way the lagoon-channel is widened and deepened. In a perfect atoll, that is, an unbroken annular reef of coral, the lagoon could not be deepened by any mere abrasion of the dead coral and removal of the detritus in suspension, but solution by carbonic acid would still come into play. It is further to be borne in mind that small lagoons are shallow and are being filled up, and that it is only the large ones, encircled by nearly continuous reefs, where the corals in the lagoon and along the margin are dead, and where the effects of solution may be conceived to have been longest in operation, that the depth of the lagoon descends below the limits at which reef-builders live.

I do not regard this solution of the difficulty as wholly satisfactory. Of the fact that dead calcareous organisms are attacked and carried away in solution by the carbonic acid of sea-water there cannot be any question, and this process must be of great geological importance. Whether the solvent action is sufficient to account for the exceptional depth of some lagoons, is still, I think, open to inquiry. It seems to me not improbable that these comparatively few deep lagoons may owe their depth partly to subsidence. But if this be the case it would lend, I am afraid, but slender support to a theory of wide oceanic depression. That there must be some areas of subsidence over the coral regions is almost certain, and the few scattered deep lagoons may possibly indicate some of these areas.

Having thus fully examined the arguments on both sides of this interesting and important question, I feel myself reluctantly compelled to admit that Darwin's theory can no longer be accepted as a complete solution of the problem of coral-reefs. No one could be more impressed than myself with the simplicity of this theory, the brilliancy of its generalisation, its remarkable fitness in geological theory, and the grandeur of the conceptions of geographical revolution to which it leads. I am fully alive to the serious changes which its abandonment will make in some departments of geological speculation. But in the face of the evidence which has now been accumulated, I can no longer regard the accepted theory as generally applicable. That it may possibly be true in some instances may be readily granted. There may be areas of subsidence, as there certainly are areas of elevation, over the vast regions where coral-reefs occur. It may be conceded that subsidence may sometimes have provided the platform whereon coral-reefs have sprung up, and may have contributed to heighten some reefs and to deepen some lagoons and lagoon-channels. But I do not believe that we are now justified in assuming subsidence to have taken place, from the mere existence of atolls and barrier-reefs. Its occurrence at any locality must be proved by evidence of special local movement. It may have gone on at many localities where atolls and barrier-reefs are found, but the existence of such reefs is no more necessarily dependent upon subsidence than upon elevation. These subterranean movements must be looked upon as mere accidents in a general process of coral growth which is wholly independent of them.

I may in conclusion refer to one or two difficulties which have long been felt to be serious drawbacks to the theory of subsidence, but which disappear when the newer views of the origin of coral-reefs are accepted. If, as Darwin supposed, the coral-islands of the Pacific and Indian Oceans represent the last peaks of submerged continents, it is incredible that continental rocks should not be found among them. The oceanic islands (except of course those composed of coral-rock) are of volcanic origin and show none of the granites, schists, and other rocks which might have been looked for on such elevated summits. They have been piled up by the accumulation of lavas and tuffs discharged from the earth's interior, and, where they occur, point to upheaval rather than subsidence. Again, as Mr. Murray has shown, the inorganic deposits of the ocean-floor are composed of volcanic debris with a singular absence of the minerals that constitute the usual crystalline rocks of our continents.

No satisfactory proofs of a general subsidence have been obtained from the region of coral-reefs, except from the structure of the reefs themselves, and this is an inference only, which is now disputed. From the nature of the case, indeed, traces of subsidence can hardly be expected. A few examples have been cited, such as the occurrence of trunks of cedar-trees in a layer of red soil at Bermuda, lying between the calcareous deposits and at a depth of 42 feet below low-water mark. This indicates a recent subsidence of that tract; but it may be merely local, and may be due to the sinking down of the roof of one of the caverns into which the limestone is so abundantly honeycombed. Occasionally along the margins of lagoons trees are found at the water edge, in a position suggestive of subsidence. But the removal of the calcareous rock by solution or wave-action might equally account for their condition.

Of elevation in the region of atolls and barrier-reefs, there is almost everywhere more or lees distinct evidence. Prof. Dana has collected the facts which prove that recent elevatory movements of unequal and local extent have occurred in all parts of the ocean.[1] Upheaval has taken place even in areas where barrier-reefs and atolls are in vigorous growth. Such an association of upheaval with an assumed general subsidence requires, on the subsidence theory, a cumbrous and entirely hypothetical series of upward and downward movements. These are unnecessary if we can be convinced that coral-reefs grow up independent of terrestrial movements, which may in one area be in an upward, in another in a downward direction. From this point of view the reefs stand up as the result of a complex series of agencies, among which the more important are on the one hand, the temperature, solvent power, currents, tides, and waves of the sea, and on the other hand, the amount and direction of the supply of pelagic food, the upbuilding of calcareous deposits to the zone of reef-builders, the outward vigorous growth of the coral-masses and their decay and death, and the solution of their skeletons in the inner parts of the reefs. All these causes are known and visibly active. Without the cooperation of any other supposed or latent force they appear to be entirely adequate to the task of building up the present coral-reefs of the oceans.

---

[1] Prof. Dana (*op. cit.*) cites examples of raised coral-reefs 250 to 300 feet ove sea-level; but we do not yet know how much of the rock is solid coral d how much may be formed of aggregated organic debris.

ARCH. GEIKIE

DR. JOHN LAWRENCE LECONTE

INFORMATION has just been received in this country announcing the death of Dr. LeConte. He was born in New York on May 13, 1825, and was the son of a distinguished officer in the United States army, himself an entomologist. He adopted the medical profession, and during the secessionist war he entered as medical officer of volunteers. The foregoing necessarily brief, specially biographic account is chiefly derived from information furnished in Dimmock's "Special Bibliography of American Entomologists, No. 1."

LeConte could have been only nineteen years old when he published his first entomological paper on certain new species of North American *Coleoptera* (*Proceedings of the Academy of Natural Sciences of Philadelphia*, vol. ii.). From that time forward a continuous series of works and papers on North American *Coleoptera* was produced by him until his death. He made a speciality of *Coleoptera*, and, with few exceptions, all his writings were devoted to that order of insects, and through his exertions the beetles of the United States are now almost as well known as are those of Europe. At the time of his death his published papers must have been nearly 200. Moreover he was the acknowledged authority in the United States on all matters coleopterological, a position which must naturally have caused him vast trouble and correspondence, sometimes with inadequate results. Latterly he worked greatly in company with Dr. G. H. Horn, of Philadelphia, a worthy follower of his tutor and a worthy successor. Their joint labours culminated *this year*, when was published ("Smithsonian Miscellaneous Collections," No. 507) a "Classification of the *Coleoptera* of North America," a volume extending to nearly 600 pages. It is needless here to refer to the revolution this work and other memoirs (chiefly by Dr. Horn) created in the minds of coleopterists as to the sequence of main divisions, &c. All working entomologists are sufficiently alive to the importance of the new ideas put forth. In fact this volume might have been considered a model of a special monograph were it not for a somewhat crude "Introduction" on insects in general that precedes the systematic portion.

In the present condition of entomological science in the United States the loss of Dr. LeConte seems almost irreparable. He and his coadjutor, Dr. Horn, and one or two others, stood almost alone amongst the prominent American entomologists in holding no special official position in connection with their subject.

LeConte once made a lengthy stay in Europe, and was well known personally in this country to all the prominent Coleopterists. Moreover he was honorary member of several of the European entomological societies, including the Entomological Society of London; his personal friends in this country were numerous. Since the death of Say (whose scattered works were carefully collated and re-edited by the subject of this notice) entomological science in America has not had to deplore so severe a loss, and Say's death was not fraught with the same significance.

R. McLACHLAN

THE LATE MR. DARWIN ON INSTINCT

AT the meeting of the Linnean Society this evening (December 6) a highly interesting posthumous paper on Instinct, by Charles Darwin, will be read and discussed. We have been favoured with an early abstract of the same, which we here present to our readers.

After detailing sundry facts with reference to the migratory instincts of different animals, Mr. Darwin proceeds to suggest a theory to account for them. This theory is precisely the same as that which was subsequently and independently enunciated by Mr. Wallace in NATURE, vol. x. p. 459. Thus, to quote from the essay: "During the long course of ages, let valleys become converted into estuaries, and then into wider and wider arms of the sea; and still I can well believe that the impulse [originally due to seeking food] which leads the pinioned goose to scramble northward, would lead our bird over the trackless waters; and that, by the aid of the unknown power by which many animals (and savage men) can retain a true course, it would safely cross the sea now covering the submerged path of its ancient journey."

The next topic considered is that of instinctive fear. Many facts are given, showing the gradual acquisition of such instinctive fear, or hereditary dread, of man, during the period of human observation. These facts led Mr. Darwin to consider the instinct of feigning death as shown by sundry species of animals when in the presence of danger. Seeing that "death is an unknown state to each living creature," this seemed to him "a remarkable instinct," and accordingly he tried a number of experiments upon the subject with insects, which proved that in no one case did the attitude in which the animal "feigned death" resemble that in which the animal really died; so that the instinct really amounts to nothing else, in the case of insects at all events, than an instinct to remain motionless, and therefore inconspicuous, in the presence of danger. From the facts given with regard to certain vertebrated animals, however, it is doubtful how far this explanation can be applied to them.

A large part of the essay is devoted to "Nidification and Habitation," with the object of showing, by an accumulation of facts, that the complex instincts of nest-building in birds and of constructing various kinds of habitations by mammals, all probably arose by gradual stages under the directing influence of natural selection.

The essay concludes with a number of "miscellaneous remarks" on instincts in general. First the variability of instinct is proved by sundry examples; next the fact of double instincts occurring in the same species; after which, "as there is often much difficulty in imagining how an instinct could first have arisen," it is thought "worth while to give a few, out of many cases, of occasional and curious habits, which cannot be considered as regular instincts, but which might, according to our views, give rise to such." Finally, cases of special difficulty are dealt with; these may be classified under the following heads:—(1) Similar instincts in unallied animals; (2) dissimilar instincts in allied animals; (3) instincts apparently detrimental to the species which exhibit them; (4) instincts performed only once during the lifetime of an animal; (5) instincts of a trifling or useless character; (6) special difficulties connected with the instinct of migration; (7) sundry other instincts presenting more or less difficulty to the theory of natural selection.

The "Conclusion" gives a summary of the general principles which have been set forth by the whole essay. This, therefore, we shall quote *in extenso*:—

"We have in this chapter chiefly considered the instincts of animals under the point of view whether it is possible that they could have been acquired through the means indicated on our theory, or whether, even if the simpler ones could have been thus acquired, others are so complex and wonderful that they must have been specially endowed, and thus overthrow the theory. Bearing in mind the facts given on the acquirement, through the selection of self-originating tricks or modification of instinct, or through training and habit, aided in some slight degree by imitation, of hereditary actions and dispositions in our domesticated animals; and their parallelism (subject to having less time) to the instincts of animals in a state of nature: bearing in mind that in a state of nature instincts do certainly vary in some slight degree: bearing in mind how very generally we find in allied but distinct animals a gradation in the more complex instincts, which shows that it is at least possible that a complex instinct might have been acquired by successive steps; and which moreover generally indicate, according to our theory, the actual steps by which the instinct has been acquired, in as much as we suppose allied instincts to have branched off at different stages of descent from a common ancestor, and therefore to have retained, more or less unaltered, the instincts of the several lineal ancestral forms of any one species: bearing all this in mind, together with the certainty that instincts are as important to an animal as their generally correlated structures, and that in the struggle for life under changing conditions, slight modifications of instinct could hardly fail occasionally to be profitable to individuals, I can see no overwhelming difficulty on our theory. Even in the most marvellous instinct known, that of the cells of the hive-bee, we have seen how a simple instinctive action may lead to results which fill the mind with astonishment.

"Moreover, it seems to me that the very general fact of the gradation of complexity of instincts within the limits of the same group of animals; and likewise the fact of two allied species, placed in two distant parts of the world and surrounded by wholly different conditions of life, still having very much in common in their instincts, supports our theory of descent; for they are explained by it: whereas if we look at each instinct as specially endowed, we can only say that it is so. The imperfections and mistakes of instinct on our theory cease to be surprising: indeed it would be wonderful that far more numerous and flagrant cases could not be detected, if it were not that a species which has failed to become modified and so far perfected in its instincts that it could continue struggling with the co-inhabitants of the same region, would simply add one more to the myriads which have become extinct.

"It may not be logical, but to my imagination it is far more satisfactory, to look at the young cuckoo ejecting its foster-brothers, ants making slaves, the larvæ of the Ichneumonidæ feeding within the live bodies of their prey, cats playing with mice, otters and cormorants with living fish, not as instincts specially given by the Creator, but as very small parts of one general law leading to the advancement of all organic bodies—Multiply, Vary, let the strongest Live and the weakest Die."

PORTO RICO

THROUGH the courtesy of Sir Joseph Hooker, we are able to publish the following interesting communication from Baron Eggers on the island of Porto Rico:—

St. Thomas, October 22, 1883

DEAR SIR JOSEPH HOOKER,—It is a long time since I wrote you last. I have meanwhile at last accomplished my long-cherished design, partly at least, of exploring the Luguillo Mountains in Porto Rico, which island I visited during April and May this year.

I spent about five weeks there, living for some time in the hut of a "fibaro" or native labourer on the Sierra, at an altitude of about 2200′, on the edge of the primeval forests that still cover all the higher part of the mountain range.

Since my return I have been busy arranging my collections, the greater part of which appears in the ninth and tenth century of my "Flora Indiæ Occidentalis Exsiccata."

As for the general character of the Sierra forests, they of course resemble in their main outlines those of the other West India Islands. There is, however, especially one feature that strikes me as being peculiar to this mountain ridge compared with the woods of other islands, for example, of Dominica. Whilst the climate is just as moist in the Sierra of Porto Rico as in that of Dominica, the forests of Porto Rico seem nearly entirely *destitute of epiphytes* with the exception of some few Bromeliads and a very rarely occurring stray orchid. But orchids in general and epiphytical ferns, such as *Trichomanes* and *Hymenophyllum*, &c., are conspicuous by their absence. Of palms I found but one species, which I have distributed in my "Flora," I believe it is a *Euterpe*, grows gregariously at an altitude from 1500′ to 3000′. No Cycads were seen at all.

On the other hand, I found several interesting trees, especially a beautiful *Talauma*, with immense, white, odorous flowers and silvery leaves, which would be very ornamental. The wood is used for timber, and called Sabino. A *Hirtella* with crimson flowers I also found rather common; it is not described in any of Grisebach's publications. An unknown tree with beautiful, orange-like foliage, and large, purple flowers very similar in shape to those of *Scævola Plumieri*, split along one side, a tall *Lobeliacea*, a large *Heliconia*, nearly allied, it seems, to *H. caribbœa*, Lam., and several other as yet undetermined trees and shrubs, are among the most remarkable things found.

On the whole I was somewhat disappointed with regard to the result of the voyage, as I had expected a greater number of novelties, as well as a richer vegetation in general, at least something like the Caribbean Islands. But these partly negative results may no doubt be of some value also in forming an idea of the West Indian flora in general. Of tree-ferns, *Cyathea Serra* and an *Alsophila* were not uncommon.

One of the most conspicuous trees in some parts is the *Coccoloba macrophylla*, which I found on my first visit to Porto Rico. This tree is found up to an altitude of 2000′, but chiefly near the coast, where it forms extensive woods in some places, which at the time of flowering, with immense, purple spikes more than a yard long, are very striking. The tree is named Ortegón by the inhabitants; it does not seem to occur on any of the British islands, but to be confined to Porto Rico and Hayti; at least I do not see it mentioned in Grisebach's "Cat. Plant. cubensium."

The people cultivate sugarcane in the plains, which are very fertile, yielding three hogsheads on an average per acre without any kind of manure. Besides this staple produce, a very good coffee is produced; it does not appear that any blight has as yet perceptibly affected the shrubs here. Rice is very commonly cultivated on the hills in the Sierra. I suppose it must be a kind of mountain variety, as no inundation or other kind of watering is used. Rice is in fact the staple food of the labourers, together with plantain and yaŭdia, *i e. Caladium esculentum*. Immense pastures of *Hymenachne striatum* (Malahojilla) occupy a part of the lowland, and feed large herds of cattle of an excellent quality. St. Thomas and the French islands all obtain their butcher's meat from

Porto Rico; I believe even Barbados comes to Porto Rico for cattle.

The island is very richly endowed by nature, but miserably governed, and the people themselves not worth a much better government, being given to gambling in the extreme throughout, thus squandering away every dollar, from the rich planter and priest down to the lowest labourer and beggar. Yet they are hospitable and very polite to strangers, with that remarkable, unchanging, inbred Spanish politeness.

It may finally interest you to hear, from the fact that you take a prominent part in the advancement of the material progress of the English West India Islands, how we are working in that respect here in St. Thomas.

I have on my estate now about 4000 Divi-Divi trees growing and doing well, except for the deer, which do much damage. On the coasts I have over 2000 cocoa-nut trees planted; cultivation of the *Sanseviera guineensis* is going on for making fibres; a large tract of land stocked with *Hæmatoxylon* I have now preserved, and try to make it a regular forest, to be cut down gradually.

In company with an engineer here I have now ordered a machine from England, Smith's fibre machine, which is being used in the Mauritius, in order to work up our immense quantity of *Agave* and *Fourcroya*, the raw material being close at hand in unlimited quantity near the sea.

I have published a couple of articles on the material resources of these islands in one of the largest Danish newspapers, of which I beg to send you a copy, in order to make private persons and Government move. Among the former a good many have started on, but, as you may perhaps have heard, governments are sometimes slow in moving, representing, as they do eminently, that great law of nature, *vis inertiæ*.

However, so far, and considering the short space of time, I am very well satisfied. I think there is a fair chance now of the West Indies in general entering upon a new prosperous career.

I am also going to try experiments with the manufacture of tannin extracts from bark of *Coccoloba*, *Rhizophora*, and the pods of the various Acacias, which are a great nuisance here on account of their rapid growth.

The *Aloe sempervirens* will also be made useful in a similar manner as in Barbados and Curaçoa, it growing here spontaneously on barren rocks. H. EGGERS

THE REMARKABLE SUNSETS

UNDER the headings of "Cloud-Glow" and "Optical Phenomena" we have published several letters already on the recent remarkable sunsets; we have received many others, the most important of which we bring together here:—

PERHAPS it will interest you and your readers to hear that the phenomenon called "cloud-glow" in your last numbers, was seen also at Berlin on the three evenings of November 28, 29, and 30. As far as I could overlook the sky, the details were almost the same as your correspondents describe them: A greenish sunset at 3.50, an unusually bright red sky with flashes of light starting from south-west. An interesting physiological phenomenon which we call "Contrast-Farben," was there beautifully illustrated by some clouds, no longer reached by direct sunlight; they looked intensely green on the red sky. At 4.30 the streets were lighted by a peculiarly pale glare, as if seen through a yellow glass. Then darkness followed, and the stars became visible. But half an hour afterwards, at 5 o'clock, the western sky was again coloured by a pink or crimson glow. Persons who were not quite sure about its direction mistook it for a Polar aurora; others spoke of a great fire in the neighbourhood. If atmospheric refraction could be neglected, the matter (whatever it may be) thus illuminated by the sun one hour after sunset and 45° above the horizon, would be found to be at a height of about forty miles! At 6 o'clock all was over. The first day (November 28) this glow was still stranger, because the lower western sky was covered by a large, dark cumulus-cloud; but besides this the three remarkable evening skies were quite like each other. ROBERT VON HELMHOLTZ

N.W. Berlin, Neue-Wilhelmstrasse 16, December 1

P.S.—To-day it rains; nevertheless an unusual brightness was to be seen in the west till 7 o'clock, which perhaps may be attributed to the same "glow."—R. v. H.

THE red glow described by your correspondents continued to be visible here every evening until yesterday (2nd inst.), and there was another fine display of *rayons du crépuscule*. Is not "cloud-glow" a misnomer as applied to what is seen in perfection only when there are no clouds, and is invisible when the clouds are thick? "After-glow" is too comprehensive an expression, as it embraces the usual effects of a brilliant sunset, and too limited, as it could not be applied to the phenomenon as recently seen before sunrise. In the absence of a scientific title for something which has been but little investigated, might not the name "upper-glow" be adopted, in contrast to the under-glow which is the predominant feature of ordinary effective sunsets. The red colour of the reflected light is in both cases I suppose equally due to diffraction, particles suspended in the air obstructing the rays of least wave-length. But in the "upper-glow" the reflecting matter is at a great height above the cloud-level, in the "under-glow" it consists of the lower surface of the clouds themselves. ANNIE LEY

December 3

Erratum.—In the first paragraph of my letter of the 27th ult. (p. 103) 2600 should be 26,000.

THE following extracts from my observations at York may assist in determining the cause of the extraordinary series of sunrise and sunset effects during the past month:—November 24: Unusual cloud tinge in morning. November 25: Similar effect in morning. From 2.45 to 3 p.m., blue sky from 10° to 25° or 30° from the sun, of a delicate rose pink. This noticed by several, when asked to say if they saw anything peculiar. It gave a greenish-gray cast to cirro-cumuli through which it was seen. Round the sun the sky looked yellowish. 5.30 p.m., "the west ruddy as from glare of fire;" not entirely gone till 6. Time of local sunset 3.38, calculated from almanac and observed sunrise on 28th.

A letter from my father, Street, Somerset, 26th, evening, speaks of "a wide arc above the sunset lit up with the most glorious pink shade. The clouds low in the horizon a stone-gray; but the most remarkable of all was a longish cloud to the north of sunset and above and beyond the circle of pink; that was a bright sage green. I never before saw such a colour in any cloud. . . . Later, rays shot up from the sun like the rays of aurora."

28th: Same pink halo at noon. Cloud-glare on morning of 26th and 27th; to-day, about 6 a.m. (sun rose at York 8.0, set 3.35). Sunset most striking; pink above, orange lower at 4.20; grass appeared of brownish sage green. At 5 p.m. lit up all over like red aurora. 29th: Same red glare, like that of a fire, at 6.20 a.m. Glare gone by 6.35; cirri in east-south-east lit up by 6.45. True sunrise glow 7.10; orange at base turned to yellow-green at 7.25, and cirri again black; relit at 7.35, with rosy tinge. Sun seen to rise clear of horizon at 8.2; Jupiter visible among faint haze until 8.13. 9.45 a.m., rosy glow round sun; 4.30 p.m., a fading ordinary sunset; 4.45, glare reappearing; 5 p.m., "finer than ever," as observed by Mrs. Clark. December 3: Remarkable lurid effects, 4.30 to 5.0 p.m. Letters from Street and Birmingham mention similar effects on the 28th and 29th. A paragraph in the *Daily News* reports them from Bideford, Devon, on Monday, 26th, soon after 5 p.m.; 27th, a.m.; and from 9.45, a "dusky orange and rosy band round the sun," till hidden by clouds at noon; 28th, p.m., 29th, a.m., and coloured "bands" again round the sun at 11 a.m. To me the glare never seemed as if reflected from cirrus clouds; it was much more like that from the smoke-originated clouds of manufacturing districts. The day effect was evidently from the same cause as the after-glow. May it not help us to connect it with the "green sun" phenomenon of India? In that case the possible connection of the latter with the volcanic eruptions of Java assumes special interest, and may give us a new insight into the upper currents of wind. We have already heard how ashes fell at great distances to windward, reckoning by the surface currents. The same upper winds, in the time that elapsed, seem to have carried lighter ashes, projected still higher, over India. May not the lightest and highest-projected, almost impalpable dust have been spread over the greater part of our hemisphere, or at any rate as far as England, whose distance from Calcutta is not double the distance from Calcutta to Java? The recent Greenland expedition has enforced the lesson of ocean soundings on the wide prevalence of such material. If this suggestion has any foundation, then the comparison to the lurid glare over cities may be a true analogy. Just as frozen fog particles form around solid nuclei of smoke, so the impalpable dust may have formed centres for cloud-formation in air strata above the normal range of clouds.

York, December 3 J. EDMUND CLARK

P.S.—December 4: My observations on last night's sunset were from hurried glances indoors. I find from Mrs. Clark that the appearances differed from the general character, being like those of Sunday evening, the 25th. She noticed, as did also another lady, the curious *green* colour of the moon. This fact was recalled to my mind to-night, when yesterday's sunset effects were repeated, the moon, to my surprise, having a most striking green tint. This was about 4.25, and it was still noticeable at 4.45.—J. E. C.

THIS singular atmospheric aspect prevails here daily at sunrise and sunset, though there seem to be indications that its splendour is on the wane. It has been visible for nearly a month, prolonging daylight upwards of an hour. At sunrise, on the 28th, the rich colours of the phenomenon again suffused the sky, and at sunset and for upwards of an hour afterwards the sky was effulgent with all the prismatic colours. The sunrise of the 29th surpassed all previous ones in magnificence, spread, and duration of colour. The day being favourable for observation, it was possible to detect a mass of attenuated, white, nebulous vapour surrounding the sun for a distance of some 30° or 40°. The sunset was less remarkable for tone and brilliancy of colour. Pearly-whites and steel-grays mostly prevailing at 4.15 p.m., a faint rosy colour suffused the whole sky. At 4.30 p.m. a band of glowing orange-coloured light, about 23° in altitude, stretched from north-west to a point near the south, and at 5.15 p.m. a remarkable body of rosy light formed in the west above the orange-coloured mass, and separated from it by a dark slate-coloured space, about 2° wide, small and pillar-shaped at first, with the apex pointing north, but soon spreading north and south. This nebulous body deepened in colour as it grew in mass till it became a remarkable volume of vivid crimson light some 5° or 6° in height, and 25° or 30° in length. At 6 p.m. the colour of the western sky had changed to orange; afterwards the colour slowly died out, and night prevailed. On the morning of the 30th ult. the glow was indistinctly apparent. In the afternoon there was a dense cloud canopy and considerable rainfall, but an orange coloured glare at sunset was discernible through the clouds. On the 1st inst. the radiance of the glow was conspicuous, and the sky richly coloured just before sunrise. At 4 p.m. the glare in the west was brilliant, with golden carmine and green colours. At 4.15 the carmine colour disappeared, the greater part of the sky became of a delicate blue, and long streaks of cirri of changeful colour lay across the sky. After many changes of tints and the appearance of the usual glow like that of a second daylight, at 5.15 p.m. the usual fiery glow rose in the west to an altitude of 25°, and continued till 6 p.m. On the 2nd, the sky was cloudy before sunrise, but the radiance was visible all the same, showing carmine and golden hues. On that morning a pale yellow coloured the sky till 11 a.m. At sunset the iridescent display was less brilliant than usual, and commenced later. But there were fiery reds, glowing yellows, and olive-greens in a sky with a detached cloud canopy. The usual fiery glow appeared at about 5.50 and prevailed till 6 p.m. On the morning of the 3rd, before sunrise, the coloured radiance reappeared in great beauty, and a yellow tint pervaded the sky throughout the day. The wind on this day was rough from the north-west. The thermometer at midday was 51°. At sunset the glow was less splendid than heretofore, and the fiery reds were dilute and diffuse. The sky was cloudy. The glow lighted up the heavens till 6 p.m. as usual. This morning (4th) the sky before sunset was resplendent with rich masses of prismatic colour. Suddenly, at 8.30 a.m., when the brilliant colours had vanished, a halo of iridescent colours encircled the sun for a short time, as though a body of vapour was swiftly traversing the sky. In a moment afterwards the colour of the sun changed to an exquisite emerald hue, staining the landscape and investing houses, buildings, glazed windows, and greenhouses with a remarkably weird aspect. Before there was well time to notice how things appeared in a bright green light, the rays of the sun changed to a deep yellow, and in a moment afterwards, as though some obscuring medium had been withdrawn, the ordinary daylight reappeared. At sunset to-day the display was magnificent in variety and tint of colour. At 4.15 the usual orange-colour bank of glowing, luminous vapour appeared in the west, extending to north-west and south-west, having above it a system of rays of a dull, fiery red. The sky was clear, flecked here and there with cirro-cumulus. At 4.45 the crescent of the moon, being just above the fringe of red light, assumed a lively green hue, and continued to exhibit the novelty of an emerald crescent till 5 p.m., when, the colour passing away, the satellite resumed its silvery hue and shone in the blue sky, while the fiery glow still lighted up the west and north-west. It seemed to me that the moon's rays neutralised in the neighbourhood the fiery tints which characterise this peculiar glow, as in the vicinity of the crescent blue sky prevailed. It may be mentioned that foreign particles are traversing the atmosphere. On July 14 black rain fell at places round this city, and some was collected at Crowle. A good observer, Mr. J. S. Haywood, the hon. secretary of the Naturalist Field Club, noticed the black sediment which the rain had deposited on the leaves of the plants and shrubs in his nursery. At the time I drew attention to the rainfall, and ventured to ascribe the discoloration to the presence of volcanic dust. It has since transpired that Krakatoa was in violent eruption from May 20 down to the fatal 26th of August, throwing up vast masses of dust. Discoloured rain again fell in the vicinity of this city on the 17th ult. J. LL. BOZWARD

Worcester, December 4

THE ruddy glow near the sun, so well described by J. Ll. Bozward in your last number (p. 102), was most conspicuous here on the 30th ult. both at sunrise and sunset. It should be examined with a spectroscope. Here there were neither clouds nor cirri visible. Yesterday it rained the whole day; towards evening the sky became clear near the zenith, heavy clouds clustering all round the horizon; above them the unexplained glow was very remarkable at sunset. If it has been observed in England on the same days, at a distance of 10° in latitude, its cause must be high in the atmosphere. Would it not be interesting to ascertain how far it has been seen, at least throughout Europe?

ANTOINE D'ABBADIE

Abbadia, near Hendaye, December 2

DURING the latter half of November we have had here also a constant succession of remarkable sunsets, and at least one sunrise of the same character. But here the effects have been accurately described by the expression "cloud-glow." Masses and streamers of cirro-cumulus vapour have hurried up from the west, evening after evening, as sunset approached, at a rate greatly in excess of the wind below, and then as the sun sank the whole sky has shone with a lurid coppery light which I have only very occasionally and partially seen before. Even when the dusk was early and thick, the same lurid glare has shone as it were behind the clouds.

HENRY CECIL

Bregner, Bournemouth, December 1

I SHOULD not have troubled you with a letter respecting the wonderful after-glows which have presented such magnificent displays during all the past week, especially on the 26th, and which have attracted such universal attention, had I not observed that no one has alluded to their appearance in the spectroscope. I made some observations on the 26th and 27th about 4.30 p.m., when the colour was at its greatest brilliancy, and was struck with the following particulars :—(1) The ordinary delicate tints of the spectrum were merged into two, a deep red and a peculiar blue-green; (2) in the middle of the red was a strong dark band; (3) on the green side of the D line, and separated from it by the light band so often conspicuous, was another band of deep citrine. The only *line* clearly distinguishable was one at the extreme end of the red.

E. BROWN

Further Barton, Cirencester, November 30

THE following note of observations of the western sky made with a pocket spectroscope on the evenings of Wednesday, November 28, and of the 4th and 5th inst., may be of interest. At about 4 o'clock—just after sunset—the band which Mr. Piazzi Smyth has termed the "low sun band," was abnormally strong, so was the line he calls *a*. The lines constantly seen in the "rain band" were not visible, and C_1 was very slight. In place of the ordinary "rain band"—a band of absorption shading off from D towards the less refrangible end of the spectrum—there was a broad band of absorption which extended nearly three-fourths of the way from D towards *a*, or nearly half way to C, its darkest part being at rather less than one-third of its width from D. From this darkest part it shaded off in both directions. In a short time this band gradually nearly disappeared, the low sun band also diminishing in intensity, while *a* became extraordinarily prominent—very dense in the middle, and slightly shaded off at both edges. At this time the yellow and orange of the spectrum seemed nearly to have disappeared, the green apparently extending to a considerable distance on the less refrangible side of D. This evening (the 5th), as Mr. Lockyer pointed out, there was also a strong band of absorption between *b* and F. I had not remarked this on the 28th or the 4th, and believe it is unusual or unusually strong.

December 5 J. F. D. DONNELLY

AN optical phenomenon has appeared at Hunstanton each afternoon commencing Sunday, the 25th ult., at about 4.30 p.m., up to and including to-day. The first appearance was a brilliant yellow light in the west, which, after a few minutes lit up the whole western horizon, the upper sky being a beautiful azure blue, showing up in contrast a few fleecy dark stratus clouds; after a few minutes the yellow light gradually turned to pink, and the horizon all round was tinged with this colour, eventually a crimson arch formed in the west, and gradually the whole thing disappeared. From the position of Hunstanton, facing west and north, remarkable and beautiful sunsets are of frequent occurrence. This morning as the sun was rising a thin layer of clouds pervaded the whole of the heavens, which were tinged with pink in every direction.

CHARLES W. HARDING

The Chase, King's Lynn, December 1

There has been much correspondence in the daily papers on the subject, and it may be useful to give here the leading points in these communications.

The phenomenon has not been confined to this country. The *Times* Rome correspondent telegraphs under date November 30:—"Yesterday evening the population of Rome was struck with admiration, mingled with awe, at the sight of a splendid phenomenon. From fifteen minutes after sunset until more than an hour later the north-western hemisphere was tinged with crimson, gradually increasing in intensity until it had the appearance of the reflection of an extensive conflagration, in front of which the tower of the Castle of Saint Angelo, the cupola of St. Peter's, and the outline of Monte Mario, as seen from the Pincio, stood out in prominent relief. Immediately above the horizon there was a broad belt of orange red, and above that another of green, surmounted by the crimson glare of the aurora. The sky of the eastern hemisphere presented a uniform sea-green tint. The phenomenon was repeated again this morning, and again this evening. A strong north wind blew all day yesterday; the sky was exceptionally clear, and the temperature was gratefully warm and balmy."

Again, an observer at Viareggio, Italy, near the Carrara Mountains, writes :—"At sunset the whole horizon, from Corsica to the Bay of Spezia, is literally bathed in a flood of red light, which, during the last few evenings, has been intensified in a remarkable degree, and prolonged till about 6 p.m., when the glow spread over the whole cloudless firmament, and was reflected on the Carrara Mountains—a truly glorious phenomenon, produced by the more than usually rarefied condition of the atmosphere under the influence of the low temperature which has prevailed for some days, the wind being north-north-west."

At the Cape also they have attracted attention. "A. D. S.," writing to the *Times* of December 4, says :—"The phenomenon in question seems to have been first noticed in this country on the evening of the 9th ult., and it recurred on several evenings during last week. A lady, who has lately been an early riser, informs me that the sky has had the same unusual light at sunrise. We have just received a letter from the Cape of Good Hope, dated November 2, in which the following passage occurs:—'We have had such extraordinary lights nearly every evening for the last five weeks. Shortly after sunset a red or yellow glow appears in the west, and it gets quite light again, and remains so for some time, and then it dies away. During the time it lasts all the flowers seem of such very brilliant colours, the pink roses especially. They look as bright as they are painted on Christmas cards, and the green of the oak trees is something wonderful. The lights appear sometimes in the morning also, an hour before sunrise, when it is generally pitch dark here.'"

So Mr. C. J. Thornton writes to the *Standard*, under date November 28, as follows:—"This afternoon I received a letter from Monghyr, Bengal, dated November 5, in which was the following passage : 'Have you seen any unusual appearances in the sky lately? For some time past in this country an extraordinary red glow has been seen in the sky just before sunrise and just after sunset. It seems to have been noticed all over India and in Egypt also, but I do not know if it has been seen in Europe. The natives are full of superstitious fears on account of it. No one, so far as I know, has been able to account for it, but several theories, more or less absurd, have been started, one trying to connect it with the eruption in Java, another with the spots on the sun, and so on. I do not know what it can be, but it is certainly very remarkable, and I never saw anything like it before.' "

A correspondent of the *Times* sends the following extract from the *Gold Coast Times* of September 14. The phenomena alluded to were seen at Cape Coast Castle :—"On the 1st or 2nd of this month the sun was described as being blue in the morning. It seems it rose as usual, and that the clouds which passed over it, from their greater rarity or density, gave it different apparent shades of rose colour, pink, and so on. After the passage of the clouds its appearance through the haze was white like the moon. In fact, an Englishman is said to have taken it for the moon."

In Paris also, and elsewhere in France, the phenomenon has been very striking.

A correspondent writing from Croydon to the *Standard*, under date November 26, says :—" At half-past three this afternoon the sky in the west quickly assumed a deep red colour, which, after some minutes, spread over the sky to a considerable distance, tinging it with a pale pink colour. This, again, in a few minutes, disappeared, and the sky assumed its normal condition."

Another correspondent on the same date, from Derby, states :—"This evening we have witnessed a most remarkable sunset, the sky being lit up with a pale bluish-yellow light, changing to orange and red."

Again, a correspondent to the same paper writing on November 28 from Skegness, Lincolnshire, says :—" Here, in the fens of Lincolnshire, where gorgeous sunsets are the rule, the phenomenon has been most remarkable, and each evening since Sunday last the heavens have presented an appearance both interesting and awe-inspiring. On Monday evening last, when the sun set at 3.57, the western heavens were all aglow until 6.30, and the rich, lurid glare of the 'after-glow' had all the appearance of an immense illumination, the rays of which, starting from the direction of the setting sun as a centre, extended well towards the zenith. The most remarkable thing was the fact that whilst the western sky was thus all aglow the stars in the northern heavens were shining as brilliantly as at midnight. The 'blood-red' appearance has been repeated during the rest of this week. The effect was altogether different from the 'Aurora Borealis,' there being an utter absence of the peculiar scintillation common to that phenomenon."

From Eastbourne, according to a correspondent there, " a considerable space above the hills where the sun had disappeared was a clear sky with no tinge of red in it, but a pale greenish-blue transparency, to describe which I can find no precise words. Across this there floated three or four opaline cloudlets, while a great mass of violet-coloured vapour lay piled up in the south-west. Above the pale and clear transparency was a broad zone of rose-colour, which seemed denser here and there, and also appeared to shoot upwards in tongue-shaped undulations. As the evening advanced, and the true sunset, at 3 57, took place, the clear sky disappeared, as if drawn down behind the hills, which the rosy zone now touched, and was gradually drawn down in its turn, but remained unfaded to the last."

Mr. Sydney Hooper, writing to the *Standard* from Ealing, says :—" In none of the correspondence on the subject of the remarkable sunsets we have had lately have I seen any reference to what strikes me as the most curious fact in connection with them, and which in my experience is quite unique. I have observed sunsets carefully for the last thirty years, and I have invariably found that the crimson glow is the last ; coming usually a considerable time after the yellow glow has faded. The crimson light is always followed by the cold gray which precedes the night, as many must have observed when the rosy light dies out from an Alpine peak. For the last few evenings, however, notably on Wednesday night, there has been a reversal of this rule. A yellow glow has first overspread the sky, extending almost to the zenith. This has gradually deepened to orange, then to crimson. The crimson has then gathered in intensity towards the horizon until it has become a deep, rich, horizontal bar, lingering long after sunset. Then came the effect which I refer to as unique. After the crimson had died away, the west was again lit up by a deep orange glow extending over half the sky, so intense in colour that the lamps showed as white light against it. This second glow is to me unaccountable, and indicates a very peculiar condition of the atmosphere. Another fact, equally remarkable, was that the whole effect was reproduced the following (Thursday) morning, but the order of the tints was, of course, reversed. At a quarter to six an exact reproduction of the orange tint of the previous evening was seen in the south-eastern sky. This was followed by the deep crimson bar low down in the horizon. Then the crimson gradually passed upwards, giving place finally to the greenish yellow with which the phenomena commenced in the evening."

NOTES

It is proposed to hold, during the year 1884, an International Exhibition, which shall also illustrate certain branches of health and education, and which will occupy the buildings at South Kensington erected for the International Fisheries Exhibition. The object of the Exhibition will be to illustrate, as vividly and in as practical a manner as possible, food, dress, the dwelling, the school, and the workshop, as affecting the conditions of healthful life, and also to bring into public notice the most recent appliances for elementary school teaching and instruction in applied science, art, and handicrafts. The influence of modern sanitary knowledge and intellectual progress upon the welfare of the people of all classes and all nations will thus be practically demonstrated, and an attempt will be made to display the most valuable and recent advances which have been attained in these important subjects. The Exhibition will be divided into two main sections, Division I. Health, Division II. Education, and will be further subdivided into six principal groups. In the first group it is intended specially to illustrate the food resources of the world, and the best and most economical methods of utilising them. For the sake of comparison, not only will specimens of food from all countries be exhibited, but the various methods of preparing, cooking, and serving food will be practically shown. The numerous processes of manufacture connected with the preparation of articles of food and drink will thus be exemplified ; and, so far as the perishable nature of the articles will admit, full illustrations will be given of the various descriptions of foods themselves. In the second group, dress, chiefly in its relation to health, will be displayed. Illustrations of the clothing of the principal peoples of the world may be expected ; and a part of this Exhibition, which, it is anticipated, will be held in the galleries of the Royal Albert Hall, will be devoted to the history of costume. In the third, fourth, and fifth groups will be comprised all that pertains to the healthful construction and fitting of the dwelling, the school, and the workshop ; not only as respects the needful arrangements for sanitation, but also the fittings and furniture generally in their effect on the health of the inmates. The most improved methods of school construction will be shown, and the modes of combating and preventing the evils of unhealthy trades, occupations, and processes of manufacture will form portions of the Exhibition. The sixth group will comprise all that relates to primary, technical, and art education, and will include designs and models for school buildings; apparatus and appliances for teaching; diagrams, text-books, &c. Special attention will be directed to technical and art education, to the results of industrial teaching, and to the introduction of manual and handicraft work into schools.

On the 22nd ult. the remainder of the furniture and stores for Ben Nevis Observatory were carried to the top under great difficulties. The party had intended to make the ascent at the beginning of the week, but, owing to the state of the weather, they could not think of it. On Thursday morning, however, although the weather was not very favourable, it was decided to make the ascent, and at 9 a.m. Mr. James M'Lean, contractor, and Alex. Turban, who is in charge of the stores, along with two assistants, started with some chairs and other stores. The first part of the journey was easily accomplished. The snow lay pretty heavy down to within a mile of Achintee farmhouse, and several deep wreaths were encountered before reaching the lake. On reaching the Red Burn they came upon a long wreath of about fourteen feet deep. The snow being somewhat soft, the party had to cut a passage through, which was a rather difficult task. Determined if possible to reach the top, they proceeded slowly, and, as they ascended, the snow was found to be deeper, in which they sometimes sank to their shoulders. Parts where the wind had driven off the snow were covered with ice, rendering the path difficult and dangerous. Their efforts were, however, ultimately crowned with success, for at 2.30 p.m., five and a half hours after starting, the party reached the Observatory. The average depth of snow on the level parts on the summit was about six feet, and round about the Observatory it was eight feet. Mr. Omond and his assistants were in excellent spirits, are very comfortable, and now feel quite at home. The party started on the return journey at 3.30, and Fort William was reached at 6.30 p.m., the whole journey, including a stay of an hour at the Observatory, occupying nine hours.

We regret to learn of the death, on the 30th ult., of the celebrated Swedish zoologist, Prof. Sven Nilsson, of the Lund University, at the age of ninety-seven.

M. Renard has communicated recently (November 3) to the Royal Academy of Brussels the results of a chemical and microscopic examination of the ashes from the great eruption of Krakatoa, which fell at Batavia on August 27 last. He finds that the volcanic dust consists mainly of glassy particles, among which may be distinguished crystals of plagioclase, often in rhomboidal lamellæ, augite, rhombic pyroxene, and magnetite. The rock which has been blown into this finely divided state presents the general mineralogical composition of the augite-andesites, but with a rather higher proportion of silica, which, on analysis, was found to amount to 65 per cent. of the whole.

A meeting will be held on Friday at the rooms of the Royal Society, Burlington House, Piccadilly, when it will be proposed to appoint a Committee, and to make such other arrangements as may be considered necessary for the successful promotion of the William Spottiswoode Memorial Fund. The chair will be taken by Prof. Huxley, President of the Royal Society, at four o'clock precisely.

The members of the Polar meteorological station which Denmark maintained at Godthaab in Greenland under the international scheme, have just returned to Copenhagen. The chief of the expedition, Lieut. A. Paulsen, reports that, having left Copenhagen on May 18, 1882, in the sailing ship *Ceres*, they arrived at Godthaab on June 14. On the voyage out observations of the temperature of the sea and air were made every hour. On the arrival out the expedition had to select the most suitable spot for the erection of the four wooden buildings brought with them, in which the magnetic and astronomical observations were to be made. A small mountain ridge near the church in the colony was chosen for this, as the preliminary researches in its neighbourhood showed that the influence of iron strata on the magnetic current was here very small. The buildings were then erected and the pillars raised on which the transit instrument, the great astronomical clock, and the eight different magnetical instruments were mounted, and simultaneously the instruments for the meteorological observations were also placed so that the weathercock and the anemometers, as well as the thermometer hut, were situated as free as possible. On August 1 the meteorological observations could be commenced, but the magnetic ones were through an accident delayed until the 7th. From that date complete observations were made in exact accordance with the international programme without interruption every hour until August 31 this year, and the expedition has thereby fully accomplished its object, viz. of obtaining a full year's magnetical and meteorological observations in this locality. A number of other scientific researches have also been pursued, of which those on the aurora borealis should particularly be mentioned. This phenomenon was frequently observed and studied during the winter, while some exceedingly valuable statistics were obtained as to the altitude of the aurora borealis above the earth's surface by measurements effected simultaneously in various places by light signals. The measurements of atmospheric electricity have also led to valuable results. It is stated to have been the best equipped Polar expedition ever despatched from Denmark. We hope soon to give further details.

The following communication from Mr. Charles Ford, of the Botanic Garden, Hong Kong, dated October 3, 1883, has been forwarded to us from Kew for publication:—"By the s.s. *Laertes* which left this place for London last week I have sent two Wardian cases of live plants, one case of living orchids, and a case of herbarium specimens, which I brought back from the Lo-Fan Mountains up the East River, and distant about sixty miles from Canton, where I spent about three weeks in August. On this excursion I travelled over about eighty miles of country after leaving the river, and consequently had a considerable amount of trouble when the natives knew I had no boat to fall back upon, and was therefore very much in their hands. I intended to make another trip up the North River during this month, but that is now impossible, as Dr. Hance, who is Acting Consul at Canton, will not apply to the Viceroy for passports for any one, and he says he is afraid it will be a long time before he will feel at liberty to do so. You have no doubt heard of the very serious trouble at Canton, in which a riot occurred and nearly twenty European residences were attacked and burnt down by the Chinese and the valuable contents of the houses carried off by the mob. There is a very hostile feeling to foreigners prevailing now amongst the Chinese, and it is considered quite unsafe to travel in the country. I was in the Lo-Fan Mountains when the trouble at Canton commenced, but no one attempted to molest me, and I returned to Canton in a passage junk with 150 Chinese on board, and no foreigner besides myself; since then, however, matters have become much worse. Mr. Sampson's herbarium and house were burnt when his house was set fire to, and Dr. Hance's, which was not more than fifty yards off, might easily have shared the same fate, but very fortunately it was spared. Dr. Hance is extremely busy with official matters, and he thinks it will be a long time before he can resume botanical work. There is an encampment of 1000

Chinese troops in the foreign settlement at Canton, and five foreign and about a dozen Chinese gunboats in the river opposite to it: all these for the protection of the foreign residents and their property. The missionaries have left the country districts, and do not expect to be able to return for many months. These things will prevent any botanical work being done in China for some time. I hope something may be done in Formosa in the beginning of next year."

LARGE use is made at the Forth Bridge Works of electricity for lighting purposes. At South Queensferry the workshops are lit up by sixteen arc lights, supplemented by a certain number of movable small incandescent lights. Outside twelve large arc lights serve to illuminate the various lines of rails and the approaches to the workshops. The offices, canteen, and other buildings are lighted throughout with Swan incandescent lights of 20-candle power, over 200 being there alone required for the purpose. The staging, which, beginning near the Hawe's Pier, extends for nearly half a mile into the Firth, has, with its approaches, twelve large lights devoted to its illumination. On the island of Inch Garvie in mid channel, four large arc lights are in use outside, and small incandescent lights in the offices and workshops, in the old castle, and in the neighbouring buildings. At North Queensferry six large arc lights serve for the outside illumination, and a number of incandescent lights for that of the interior of the offices and workshops. Nowhere is a dangerous degree of electric pressure allowed; and in all interiors, workshops, or operations under water the limit is but little more than one-half of that permitted by the Board of Trade in their provisional orders for dwellings in towns.

THE mathematical magazine conducted under the name of the *Analyst* for the past ten years, by Mr. J. E. Hendricks, will, we learn from *Science*, be continued under the editorial charge of Ormond Stone, Professor of Astronomy, and William M. Thornton, Professor of Engineering, with the title, *Annals of Mathematics, Pure and Applied*. The numbers will be issued at intervals of two months, beginning February 1, 1884. In scope the journal will embrace the development of new and important theories of mathematics, pure and applied; the solution of useful and interesting problems; the history and bibliography of various branches of mathematics; and critical examinations and reviews of important treatises and text-books on mathematical subjects. The office of publication will be at the University of Virginia.

DR. HOLUB has left England on his expedition to the interior of Africa. He leaves for this journey of a year accompanied by his wife and eleven good servants, including a carpenter, a waggonmaker, a blacksmith, a gunmaker, a tailor, and a butcher, besides his black servant-girl and a dog. In South Africa he will increase his staff by nineteen, and afterwards in Central Africa by forty more black servants.

IT is reported from the Storelvdal, a valley in Central Norway, between 61° and 62° N. lat., that the snow during the night of November 17 became covered with a gray and black layer of dust. No scientific investigation of the phenomenon has as yet been effected.

THE report of the death of Julius Payer, the discoverer with Weyprecht of Franz Josef Land, is, we are glad to say, without any foundation.

THE Annual Report for 1882–83 of the Liverpool Geological Association reports favourably, we are glad to see, on the position and work of that society.

THE Report of the Smithsonian Institution for 1881 shows how admirably that many-sided organisation continues to carry on its invaluable work. The museum in its various departments is constantly increasing; the library will soon be almost without a rival; while a successful chemical laboratory has been added to the other resources of the institute. The appendix, containing as it does a record of progress in all departments of science by specialists, is of great utility; while the special papers on anthropology continue to be a well-known feature of the Report. The Report, like the Institution, reflects the greatest credit on its secretary, Prof. Spencer Baird.

THE additions to the Zoological Society's Gardens during the past week include a Moorhen (*Gallinula chloropus*), British, presented by Mr. T. E. Gunn; two Common Wolves (*Canis lupus* ♂ ♀), European, a Dufresne's Amazon (*Chrysotis dufresniana*) from South-East Brazil; a Bell's Cinixys (*Cinixys belliana*) from West Africa, two Carp (*Cyprinus carpio*) from British fresh waters, purchased; an Indian Gazelle (*Gazella bennetti*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—The following are Greenwich times of geocentric minima of *Algol*, during the first quarter of 1884: the later observations of Prof. Julius Schmidt have been brought to bear upon the predictions.

		h.	m.			h.	m.			h.	m
Jan.	10 ...	13	35	Feb.	2 ...	12	9	March	13 ...	15	38
	13 ...	10	24		5 ...	8	58		16 ...	12	28
	16 ...	7	13		8 ...	5	47		19 ...	9	17
	30 ...	15	19		22 ...	13	53				
					25 ...	10	43				
					28 ...	7	32				

According to Mr. Knott's observations of U Cephei, 1881-1883, a minimum is indicated on January 5 at 15h. 21m. G.M.T., the period being 2d. 20h. 48·9m. The ephemeris published in the *Vierteljahrsschrift* gives it 1h. 10m. earlier; but it is not stated upon what elements this rests.

Minima of S Cancri occur on December 31 at 8h. 41m., January 19 at 7h. 57m., February 7 at 7h. 12m., and February 26 at 6h. 28m. G.M.T.

The fine variable R Leonis will be due at maximum on February 23, and *Mira Ceti* on March 11.

THE FIRST COMET OF 1798.—A recalculation of the elements of the orbit of this comet, made by Mr. Hind from Messier's observations on April 12, 13, 14, May 1, 2, 3, and May 20, 21, 22, as they are given in Zach's *Allgemeine Geographische Ephemeriden*, vols. i. and ii., does not lead to any suspicion of ellipticity, which is rather confirmatory of the view taken by Dr. Harzer as to its non-identity with the greatly perturbed comet of Brorsen (1846 III) to which reference was lately made in NATURE. The new orbit is as follows:—

Perihelion passage 1798, April 4·51482 Paris M.T.

	°	′	″	
Longitude of perihelion	105	5	43	Mean Equinox 1798·0
,, ascending node	122	7	22	
Inclination	43	48	1	
Log. perihelion distance	9·6857689			

Motion—direct.

The error in longitude for the second normal is − 19″; the latitudes agree.

THE GREAT COMET OF 1882.—We do not hear that this comet has been recognised since its conjunction with the sun. As was pointed out in this column, it was just possible that it might have been re-observed as the earth somewhat overtook it in its orbit, between the beginning of September and the end of last month. On November 30 the distance was at a minimum of 5·708, and is once more on the increase.

The comet was seen at the Observatory of Cordoba until June 1; the last complete observation for position was made there on May 26, when the distance from the earth was 5·048. There is no parallel to this in the whole history of cometary astronomy, except in the case of the very exceptional comet which was observed in 1729 and 1730; at the time of Cassini's last observation this body was distant from the earth 5·135.

Between the first accurate observation at the Royal Observatory, Cape of Good Hope, on September 7, 1882, and the Cordoba observation above referred to on May 26, 1883, the comet described an orbital arc of more than 340°. The ellipse deduced by Kreutz from observations to November 14 assigns a period of 843 years; that by Fabritius, from observations to March 3, one of 823 years; but we may soon hope to see the result of a definitive discussion of the whole series of observations.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY

THE Anniversary Meeting of the Royal Society took place as usual on St. Andrew's Day, November 30, when the President, Prof. Huxley, delivered his address; after which the Fellows elected the officers of the Society for the year, whose names we have already given in NATURE, Nov. 8, p. 43. The following is Prof. Huxley's address:—

It will be as much in consonance with your feelings as it is with my own that the first sentences of this address should give utterance to our sense of the calamity which befell us during the recess.

On June 27 our honoured and loved President, William Spottiswoode, fell a victim to that cruel malady, typhoid fever, which is at once the scourge and the reproach of modern civilisation; and we were bereaved of a chief of whom all those who had the highest interests of this Society at heart hoped that he would continue for many a year to discharge the responsible and laborious duties of his office with that broad intelligence, that faithful diligence, that inexhaustible patience and courtesy, which were so characteristic of the man.

Every one of the Fellows of the Society in whose hearing I speak knows that these are no words of conventional eulogy, as of a customary epitaph. But it is only those of us who worked with our late President in the Council, or as officers of the Society, who are in a position fully to appreciate his singular capacity for the transaction of business with clear judgment and rapid decision, and yet with the most conscientious consideration of the views of those with whom he was associated.

And I may add that it is only those who enjoyed Mr. Spottiswoode's intimate friendship, as it was my privilege to do for some quarter of a century, who can know how much was lost when there vanished from among us that rare personality, so commingled of delicate sensitiveness with marvellous self-control, of rigid principle with genial tolerance, of energetic practical activity with untiring benevolence, that it always seemed to me the embodiment of that exquisite ideal of a true gentleman which Geoffry Chaucer drew five hundred years ago:—

> "... He lovede chyvalrye,
> Truthe and honour, fredom and curtesie.
>
> . . . . . .
>
> And though that he was worthy he was wys,
> And of his port as meke as is a mayde.
> He never yit no vilonye ne sayde
> In al his lyf unto no maner wight.
> He was a verray perfight gentil knight."

It is not for me to pass any judgment upon Mr. Spottiswoode's scientific labours; but I have the best authority for saying that having occupied himself with many branches of mathematics, more especially with the higher algebra, including the theory of determinants, with the general calculus of symbols, and with the application of analysis to geometry and mechanics, he did excellent and durable work in all; and that, in virtue of his sound and wide culture, his deep penetration, and the singular elegance with which he habitually treated all his subjects, he occupied a place in the front rank of English mathematicians.

The interment in Westminster Abbey of one who, though compelled to devote a large share of his time to business, was a born man of science, and had won himself so high a place among mathematicians, was doubtless grateful to us as men of science; it could not but be satisfactory to us as Fellows of the Royal Society that, on the rare occasion of the death of our President in office, the general public should show its sympathy with our bereavement; yet as men I think it is good to regard those solemn and pathetic obsequies as the tribute which even our busy, careless, cynical, modern world spontaneously pays to such worth and wisdom, to such large humanity and unspotted purity as were manifested in the "very perfect gentle knight" who so well represented the chivalry of science.

The total number of Fellows deceased during the past year amounts to twenty; a large inroad upon our ranks in mere numbers, an exceptionally severe mortality if we consider the scientific rank of many names in the death-roll. Almost at the same time with Mr. Spottiswoode's untimely death we lost, at the ripe old age of ninety, a very distinguished Fellow and former President of this Society, Sir Edward Sabine. It is said that the average age of Fellows of the Royal Society is greater than that of any body of men in Europe; and it is certainly a remarkable fact that one who so long presided over us in this generation should, as a man of thirty years, have been the contemporary of Sir Joseph Banks, who became our President more than a century ago. And nothing can give a more striking exemplification of the gigantic progress of physical science in modern times than the fact that the discovery of oxygen by Priestley, and that of the composition of water by Cavendish, fall within the period of Sir Joseph Banks's presidency, while Black's work was but a score years earlier. We are as it were but two Presidents off the budding of modern chemistry, as of many another stately growth of the tree of natural knowledge.

Sir Edward Sabine's long services to this Society, first as Treasurer and then as President, deserve more than a passing allusion; but for a due appreciation of them, no less than of his great labours in terrestrial magnetism, I must refer you to our obituary notices.

By the unexpected death of Prof. Henry John Stephen Smith the University of Oxford lost one of the most distinguished, as he was one of the most influential, among those who have guided its destinies during this generation, and a capacity of the first order, not yet weakened by the touch of time, has disappeared from the ranks of the foremost mathematicians of Europe.

As Chairman of the Meteorological Committee, Prof. Smith rendered invaluable services to that body; and we have all a grateful recollection of the readiness with which his knowledge and sagacity were brought to our aid in Council and in Committee.

For the rest, I dare add nothing to that which has been said of him by our late President in that just and loving appreciation of his friend, which is now touched with a sadder gravity and a deeper pathos.

It is difficult to say of Prof. Smith whether he was more remarkable as a man of affairs, of society, of letters, or of science; but it is certain that the scientific facet of his brilliant intelligence was altogether directed towards those intelligible forms which people the most ethereal regions of abstract knowledge. In Sir William Siemens, who but the other day was suddenly snatched from among us, we had a no less marked example of vast energy, large scientific acquirements, and intellectual powers of a high order, no less completely devoted, in the main, to the application of science to industry.

I believe I am expressing the opinion of those most competent to judge, when I say that Sir William Siemens had no superior in fertility and ingenuity of invention; that hardly any living man so thoroughly combined an extensive knowledge of scientific principles with the power of applying them in a commercially successful manner; and that the value of his numerous inventions must be measured, not merely by the extent to which they have increased the wealth and convenience of mankind, but by the favourable reaction on the progress of pure science which they, like all such inventions, have exerted, and will continually exert.

Time permits me to be but brief in alluding to the remainder of our long list of deaths. But I may not omit to mention that we have lost a distinguished mathematician in Prof. Challis; in Mr. James Young, a chemist whose skilful application of theory to practice founded a new industry; in Mr. Cromwell Varley, an ingenious inventor; in Lord Talbot de Malahide, a warm friend of science and a zealous promoter of archæological research; in Mr. Walker, an eminent engineer; in Mr. Howard, an eminent quinologist; and in the Rev. Dr. Stebbing, an accomplished and amiable man of letters, who for very many years filled the honourable, but not very onerous, office of Chaplain to the Society.

And it would ill become us, intimately connected as this Society always has been, and I hope always will be, with the sciences upon which medicine bases itself, to leave unnoticed the decease of the very type of a philosophical physician, the venerable Sir Thomas Watson.

Two well-known names have disappeared from among those of the eminent men who are enrolled upon our foreign list; the eminent physicist, Plateau, and the no less distinguished anatomist and embryologist, Bischoff.

I now beg leave to bring under your notice a brief general review of the work of the Society during the past year.

The papers printed in the *Transactions* for 1882 and 1883 will occupy two volumes, of which three parts, containing 1038 quarto pages and fifty-two plates, have already been published. Two parts more, to complete 1883, will shortly be published.

The *Proceedings*, which steadily increase in size from year to year, amount during the past year to 780 octavo pages, with four plates and numerous engravings.

You are aware that nothing is printed in the *Proceedings* or in the *Transactions* except by the authority of the Council, which, in the latter case, calls in the assistance of at least two carefully-selected and independent referees, by whose advice it is in practise, though not necessarily, guided. I am inclined to think that Fellows of this Society who do not happen to have served on the Council, are little aware of the amount, or of the value of the conscientious labour which is thus performed for the Society by gentlemen whose names do not appear in our records. And I trust I may be forgiven for stepping beyond precedent so far as to offer our thanks for work which is always troublesome and often ungrateful; but, without which, the contributions to our pages would not maintain the high average of excellence which they possess.

Among the points of importance, by reason of their novelty or general significance, which have been laid before us, much interest attaches to the result brought out in Prof. Osborne Reynolds's "Experimental Investigation of the circumstances which determine whether the motion of water shall be direct or sinuous, and of the law of resistance in parallel channels;" which shows that when the conditions of dynamical similarity are satisfied, two systems, involving fluids treated as viscous, may be compared (as regards their effects) even when the motions are unstable; and that if any one of the two systems is in the critical state separating stability from instability, so will be the other.

Last December, Dr. Huggins presented a note on "A Method of Photographing the Solar Corona without an Eclipse," which had so far proved successful, under the unfavourable circumstances in which he had put it in practice, as to lead to the hope that, under better conditions of atmosphere and elevation, the corona might be photographed, from day to day, with so much accuracy as to preserve a clear record of the changes which it undergoes. And, as the photographs taken during the eclipse at Caroline Island show a condition of the corona, intermediate between those exhibited by Dr. Huggins's photographs at periods antecedent and subsequent to the Caroline Island observations, there is reason to believe that this hope is well based, and that a new and powerful method of investigation has been placed in the hands of students of solar physics.

Lord Rayleigh and his sister-in-law, Mrs. Sidgwick, have made a very elaborate determination of the relation between the ohm and the British Association standard of electrical resistance.

With respect to those branches of knowledge on which I may venture to offer an opinion of my own, I may say that, though our records show much useful and praiseworthy work in biological science, the only event which appears to me to call for special remark is the opening of an attack upon a problem of very great interest, one which, in fact, goes to the root of the question of the fundamental unity of the two great embodiments of life—plants and animals.

The well-known phenomena presented by many plants, such as the sensitive plant and the sun-dew, our knowledge of which was so vastly extended by Darwin, abundantly prove that the property of irritability, that is, the reaction of a living part, by change of form, upon the application of a stimulus to that part, or to some other part in living continuity with it, is not confined to animals.

But, in animals, the connection of the part irritated with that which changes its form is always effected by a continuity of more or less modified protoplasmic substance, and reaction takes place only so long as that continuity is unimpaired; while, hitherto, the protoplasmic cell-bodies of plants have appeared to be isolated from one another by the non-protoplasmic cell-walls in which they are inclosed.

It is as if, in the one case, there was a continuous bond of conducting substance between the point of irritation and the point of contraction; while, in the other, there was a chain of pellets of protoplasmic substance, each inclosed in a coat of a different nature.

Now, Mr. Gardiner, in his paper "On the continuity of the Protoplasm through the Walls of Vegetable Cells," brings forward evidence, based chiefly upon the careful use of special reagents, that, in the sensitive cushions of certain plants and in other situations, the vegetable cell-wall is pierced by minute apertures, and that these are traversed by threads of protoplasm, which connect the cell-body of each cell with those of its neighbour, and thus establish, as in animals, a continuity of protoplasmic substance between different parts. Other observers are working at the same subject, and we may hope that, before long, great light will be thrown upon many hitherto puzzling questions in vegetable physiology.

The Committee of the Royal Society, in the hands of which the Lords of the Treasury have placed the administration of the funds devoted to the publication of the work of the *Challenger* expedition, report that, under the careful and vigorous direction of Mr. Murray, this great undertaking is making rapid progress.

Mr. Murray informs me that thirty-eight reports have, up to this time, been published, forming eight large quarto volumes, with 4195 pages of letterpress, 488 lithographic plates and other illustrations. Thirty-four of these memoirs are on zoological, four on physical subjects. Nine reports are now nearly all in type, and some of them partly printed off. These will be published within three months, and will form three zoological volumes, with 230 plates and many woodcuts, and one physical volume, with many diagrams and maps; this latter volume will contain the report on the composition of ocean water, the specific gravity and temperature observations.

A considerable part of the general narrative of the cruise is now in type, and nearly all the illustrations are prepared. The narrative will extend to two volumes, and it is expected they will be ready for issue in May or June, 1884.

The work connected with the remaining forty-two special reports is, in most instances, progressing satisfactorily. Portions of the manuscript for three of the larger memoirs have been received and put in type, and the manuscript of many others is in a forward state. For these memoirs, 386 lithographic plates have been printed off and delivered to the binders; 404 others are now on stone, and the drawings for many more are being prepared. It is estimated that the whole work connected with the Report will be completed in the summer of 1887.

In his Address, last year, the President gave the Society a full account of the changes which had taken place in the administration of the Government Fund—technically termed a grant in aid of this Society—though, as you are aware, the Royal Society, while willingly accepting the burden and the responsibility of administrator of the aid granted by the State to science, is in no sense pecuniarily benefited by the grant.

A somewhat novel and extremely useful employment has been given to part of the fund by deciding to defray the expenses of adequately skilled persons who have undertaken to visit distant countries for the purpose of investigating certain interesting biological questions on the spot, and of procuring and transmitting to observers at home specimens prepared and preserved by those refined modern methods which can be satisfactorily carried out only by persons who are well versed in the practice of such methods.

Mr. Adam Sedgwick has thus been enabled to proceed to the Cape of Good Hope for the purpose of completing our knowledge of the singular genus *Peripatus*, so well studied by Prof. Moseley, and afterwards by our lamented Fellow, Balfour; and Mr. Caldwell, similarly aided, is now in Australia, devoting himself to the elucidation of the embryology of the marsupial quadrupeds of that region, a subject of which at present we know little more than was made known in the *Transactions* of this Society half a century ago by Prof. Owen.

It certainly was high time that British science should deal with a problem of the profoundest zoological interest, the materials for the solution of which abound in, and are at the same time almost confined to, those territories of the Greater Britain which lie on the other side of the globe.

Many years ago the late Mr. Leonard Horner communicated to the Society the results of a series of borings which he had caused to be made in the upper part of the delta of the Nile, with a view of ascertaining the antiquity of the civilisation of Egypt. Since that time Figari Bey, an Italian geologist in the service of the Egyptian Government, made and published the results of a large series of borings effected in different parts of the delta, but his work is hardly on a level with the requirements of modern science.

It has been thought advisable therefore to take advantage of the presence of our troops in Egypt in order to carry out a series of borings across the middle of the delta, in the full expectation that such borings, if made with proper care and carried down to the solid rock, will afford information of the most important character, and will throw a new light upon the natural and civil history of this unique country. I am glad to say that the representations which the President and Council made to the War Office on this subject were most favourably received, and that instructions were at once sent to the officer commanding the Engineers to undertake the operations which they recommended. I trust that, before long, information will reach us which will be of no less interest to the archæologist than to the geologist.

While I am speaking of Egypt, I may perhaps be permitted to express a regret that the admirable energy of the Government in taking measures to make the recent advances of medical science available during the late outbreak of cholera in that country, was not extended beyond the purely practical side of the matter, or, perhaps, not so far as the practical side in the proper sense; for until we know something about the causes of that terrible disease, our measures for prevention and for cure will be alike leaps in the dark.

Those who have looked into the literature of cholera may, perhaps, be disposed to think that a new search after its cause will add but another to the innumerable wild hypotheses which have been set afloat on that topic; and yet devastating epidemics, like the pebrine of the silkworm, so similar in their fatality and their apparently capricious spread, that careful investigators have not hesitated to institute a detailed comparison of the phenomena of this disease with those of cholera, have been proved by Pasteur to be the work of microscopic organisms; and hardly less fatal epidemics, such as splenic fever, have been traced to similar agencies. In both these cases, knowledge of the causes and of the conditions which limit the operation of the causes, have led to the invention of effectual methods of cure. And it is assuredly, in the present state of science, something more than a permissible hypothesis, that the cause of cholera may be an organic living *materies morbi*, and that the discovery of the proper curative and prophylactic measures will follow upon the determination of the nature and conditions of existence of these organisms.

If this reasoning is just, it is certainly to be regretted that the opportunity of the outbreak of cholera in Egypt was not utilised for the purposes of scientific investigation into the cause of the epidemic. There are able, zealous, and courageous young pathologists in this country who would have been willing enough to undertake the labour and the risk; and it seems a pity that England should leave to Germany and to France an enterprise which requires no less daring than Arctic or African exploration, but which, if successful, would be of a thousand times more value to mankind than the most complete knowledge of the barren ice wastes of the Pole or of the sweltering barbarism of the equator.

It may be said that inquiries into the causation of cholera have been for some years conducted in India by the Government without yielding any very definite result. But this is perhaps rather an argument in favour of, than against, setting fresh minds to work upon the problem.

In December last year the President received from the Lords of the Treasury a letter, addressed to their Lordships by the Lords of the Committee of the Privy Council on Education, recommending to the favourable consideration of the Treasury a memorial from the Solar Physics Committee, suggesting the organisation of an expedition for the purpose of making observations during the solar eclipse of May 5, 1883; and the President was requested to communicate his views upon the subject to the Treasury.

After careful consideration, the President and Council reported in favour of the projected expedition; but they added that they did so on condition of its being possible to find some one, whose position in the scientific world would command the confidence of the public, to take charge of the expedition. Unfortunately, for one reason or another, none of the men of science who fulfilled this condition were able to go; and, at the meeting of Council of January 18, the projected expedition was abandoned. The President was, however, requested to place himself in communication with the American authorities, and to ascertain from them whether a photographer and assistant could be allowed to accompany their expedition to Caroline Island. On doing so, he at once received an invitation for two observers; who were accordingly sent out, their expenses being defrayed, partly by a contribution from the Government grant, and partly by a special sum of 500*l.* provided by the Treasury.

I am indebted to Mr. Lockyer for the following list of photographs taken by the observers:—

1. Six good photographs of the corona, exposures varying from two to sixty seconds, giving coronal detail from near the limb to end of streamers. That the limit of the corona has been photographed is shown by the manner in which the light of the sky has impressed itself on the plate.
2. Three large photographs showing the details of the corona close to the limb.
3. Good photographs of the spectrum of the corona, showing a great number of coronal lines and very faint Fraunhoferic lines.
4. Photographs taken on a moving plate in integrating spectroscope, from one minute before to one and a half minute after totality, showing the most prominent lines of the reversion spectrum. These lines belong mainly to hydrogen.
5. Photographs taken with first-order grating, before, during, and after totality. These show H and K, near the limb, throughout the whole of totality.
6. Photographs taken with a dense prism spectroscope before, during, and after totality. These photographs also give some of the prominent lines of the reversion spectrum.
7. Two photographs taken in the prismatic camera on plates sensitive to ultra-red rays. Results comparatively indifferent on account of the absence of prominences.

The arrangements made for obtaining a series of circumpolar observations in meteorology and magnetism were fully described in the Presidential address of last year. I am glad to be able to report that the English party, under Capt. Dawson, has successfully achieved its mission and has returned to this country. Capt. Dawson speaks very gratefully of the efficient assistance which he received from the Canadian authorities and from the Hudson Bay Company.

The responsibility for the transaction of the ordinary work of the Society rests with the Council and the officers, of whom the President is only one, and I may be allowed to say by no means the most important, the heaviest part of the burden of the executive resting upon the Secretaries. But your President is, in virtue of his office, a member of two public bodies whose functions in relation to science are of great importance; and I follow the excellent precedent set by my predecessor in considering it my duty to acquaint the Fellows of the Society with any occurrence, bearing on the interests of science, which has come under my cognisance, as a Trustee of the British Museum and as a member of the Council and Executive Committee of the City and Guilds Institute.

In the first-named capacity, I am glad to be able to announce that the transference of the vast zoological, botanical, geological, and mineralogical collections from Bloomsbury to the New Natural History Museum is now accomplished; and that it has been effected to the great credit of all concerned, with no greater mishap than the fracture of a bottle or two.

The advantages which will accrue to zoologists, botanists, and mineralogists from the re-arrangement of this vast assemblage of the objects of their studies, in such a manner as to be accessible to every investigator, cannot be over-estimated. The Natural History Museum at South Kensington is, in fact, a library of the works of nature which corresponds in value, in extent, and in the purposes to which it should be applied, to the vast library of the works of men which remains at Bloomsbury.

In making this collection of use to the world of science by the publication of complete catalogues of its contents, and of systematic monographs upon particular groups; and to the nation at large, by the composition of guide books calculated to afford the ordinary visitor an insight into the plan of the mighty maze of nature, the officers in charge of the Natural History collections have before them a task, the due performance of which, whatever their abilities, or their number, or their industry, will tax their energies to the utmost. It is in this way that, in the discharge of their proper duties, they may render services of the highest value alike to pure science and to the diffusion of knowledge among the people, out of whose resources the great institution to which they belong is supported. And I trust that no mistaken view of the functions of the officers of the Museum, which no more embrace oral instruction in science than those of the officers of the Library comprehend oral instruction in literature, may lead to the imposition of duties, foreign to their proper business, upon the already overburdened staff of keepers and their assistants.

In Francis Bacon's apocalypse of science, the "New Atlantis," the Father of Solomon's House—he, whose countenance was "as if he pitied men,"—declares that the end of that foundation is "the knowledge of causes and secret motions of things, and the enlarging of the bounds of human empire to the effecting of all things possible."

I think that the Chancellor would have acknowledged the New Natural History Museum to be a goodly wing of such a House, devoted to the former of the objects which he mentions; but, it may be, that his practical mind, looking always to fruit, and caring for light chiefly as something essential to fruit-bearing, would have been even better satisfied with another building hard by, which has been devoted to the encouragement of those applications of science through which human empire is directly extended, by the well-directed munificence of the City and Guilds of London.

This building, destined for a central institution in which ample provision shall be made for thorough and practical training in so much of the principles and the methods of the physical sciences as is needful for those who aspire to take part in the development of arts and manufactures, has been completed at a cost of more than 70,000*l.*, while 20,000*l.* has yet to be spent upon fittings and appliances, and the working expenses, if the scheme is to be fully developed, cannot be estimated at less than 10,000*l.* a year.

Having already been called upon to take an active part in the deliberations of the committees charged with the carrying out of this great work, I think I am justified in expressing the hope, and indeed the confident expectation, that, before long, this new Technical College will be in full activity; and that, for the first time in our history, there will be called into existence an institution in which, without leaving this country, masters, managers, and foremen of works will be enabled to obtain thorough instruction not only in scientific theory, but in the essential principles of practice; and a machinery will be created, by which the poorest working lad in a manufacturing town, if he have ability and perseverance, may be brought within reach of the best technical education that is to be had.

There can be no doubt that the founders of the Royal Society had prominently before their minds the intention of promoting the useful arts and sciences "that so (in the language of the draft of the preamble to the first charter, which is said to have been drawn up by Sir Christopher Wren) by laying in a stock, as it were, of several arts and methods of industry, the whole body [of the nation] may be supplied by a mutual commerce of each other's peculiar faculties, and, consequently, that the various miseries and trials of this frail life may be, by as many various expedients ready at hand, remedied or alleviated, and wealth and plenty diffused in just proportion to every one's industry, that is, to every one's deserts." It was the wish of King Charles the Second that all patents for inventions should be examined by the Royal Society; and, so late as the reign of George the Second, the Society actually performed this duty. The steam-engine itself may be said to have made its *début* before the Royal Society, when Savery exhibited his working model to the Fellows in 1699.

But the subsequent history of natural knowledge has shown that, as in the moral world, those who seek happiness through well-doing are less likely to obtain that reward than those who try to do well without thinking what may come of it; so, in the world of science, those whose vision is fixed on useful ends are often left poor and bare, while those who strive only after the advancement of knowledge, scatter riches along their path, for the whole world to pick up. The Royal Society has chosen the latter course, and I trust it may never swerve from it. But I think that our warmest sympathy is due to the efforts of those who translate the language of the philosopher into that of the workshop; and by thus ameliorating "the miseries and toils of this frail life," and "diffusing wealth and plenty," are executing that part of the first design of this Society, with which we, as a body, have long ceased to occupy ourselves.

It was not as your President, but as one of the Special Commissioners appointed by the Government, that I had some slight share in another considerable undertaking directed towards the improvement of industry. But the future of the fisheries is so closely connected with the advancement of certain branches of zoological science, that I may be permitted to advert to the great success of the International Fisheries Exhibition; and to express my belief that, in accordance with the intimation contained in the speech of H.R.H. the Prince of Wales at the closing of the Exhibition, there will grow out of it an organisation which will provide for the application of science to the improvement of the fisheries.

In conclusion, gentlemen, I think that it is proper on my own behalf, as it is certainly due to you, that I should advert to the exceptional circumstances which have brought about my present occupation of the Presidential office.

The eleventh section of the sixth chapter of the statutes provides for the occurrence of a vacancy in the Chair, whether by death or by resignation, as follows:—

"Upon any vacancy in the President's place occurring in the intervals of the anniversary elections, the Treasurer, or in his absence one of the Secretaries, shall cause the Council to be summoned for the election of a new President, and the Council meeting thereupon in the usual place, or any eleven or more of them, shall proceed to the said election, and not separate until the major part of them shall have agreed upon a new President."

This statute is substantially, and, to a great extent, verbally, identical with the twelfth section of the seventh chapter of the original statutes of 1663.

Before the present year, five occasions had arisen on which it became necessary to put the provisions of the statute into effect.

Sir Isaac Newton died while President in 1727; the Earl of Morton in 1768; Mr. West in 1772; and Sir Joseph Banks in 1820; while Sir Humphry Davy resigned in 1827. On each of these occasions a new President was at once appointed by the Council, endowed with all the privileges and powers of the office; and, like every other officer, however appointed, he vacated his office on November 30 following, when the Fellows sometimes elected him for the succeeding year, and sometimes did not.

These precedents were strictly followed on the present occasion. A Council had been summoned, in ordinary course of business, for June 28; but, as the President died on the 27th, it was deferred until the following Thursday, when it was supposed the interment would have taken place. In consequence of the delay inseparable from a public ceremony, however, it so happened that the funeral did not take place until noon of July 5; and I have known few sadder scenes than the gathering of the Council, fresh from the unclosed grave of their President, for the performance of the duty, imposed upon them by the statutes, of choosing his successor from their own number, before they should separate.

The Council did me the great honour of selecting me for the office; and now, on this next following St. Andrew's Day, my tenure, like that of the Treasurer and Secretaries, lapses, and it is for the Fellows of the Society to say who shall be their officers until the next Anniversary Meeting.

Having served several years, in another capacity, with three out of four of my present colleagues, and having every reason to believe that the Fellows of the Society, at large, see good reason to set the same high value upon the services of all of them as I do, I do not find myself able to imagine that you will fail to desire that those services shall be continued; but I have not the least difficulty in conceiving that the Fellows of the Society may think many of their number better fitted for the eminent place of the President than myself.

I should be extremely ungrateful to my colleagues of the Council, who have again honoured me by presenting me for election by the Fellows, if I were to let fall even a hint of the extent to which I share that opinion; but I think it may be permitted me to say that, should you think fit to give effect to it, there is no one who will more cheerfully acquiesce in your decision than I shall.

To a man like myself, who neither possesses, nor seeks, any other distinction than that of having done his best to advance knowledge and to uphold the dignity and the authority of science against all comers, the Presidency of this Society is the highest dignity which he can attain, whatever else may befall him.

But, gentlemen, as men of science, you know better than I can tell you, that there are things of more worth than distinction. I am within measurable distance of the end of my career; and I have long looked forward to the time when I should be able to escape from the distractions and perturbations of the multitudinous affairs in which I have been so long entangled, to that student life from which the Fates have driven me, but to which I trust they may, for a little space, permit me to return.

So that I am sure you will neither misunderstand me, nor mislike my directness of speech, when I say that, if it please you to believe that the interests of science and of the Royal Society will be advanced by maintaining me in the very distinguished position which I at present occupy, I will do my best to justify your confidence; but if, as may well be, you think that some other Fellow of the Society will serve these interests better, I shall, with a light heart, transfer to him the honourable burden, which I have already borne long enough to know its weight.

I now proceed to the presentation of the medals which have this year been awarded by the Council.

The number, the variety, and the importance of Sir William Thomson's contributions to mathematical and experimental physics are matters of common knowledge, and the Fellows of the Society will be more gratified than surprised to hear that the Council have this year awarded him the Copley Medal, the highest honour which it is in their power to bestow.

Sir William Thomson has taken a foremost place among those to whom the remarkable development of the theory of thermodynamics and of electricity in the last forty years is due; his share in the experimental treatment of these subjects has been no less considerable; while his constructive ability in applying science to practice is manifested by the number of instruments, bearing his name, which are at present in use in the physical laboratory and in the telegraph office.

Moreover, in propounding his views on the universal dissipation of energy and on vortex motion and molecular vortices, Sir William Thomson has propounded conceptions which belong to the *prima philosophia* of physical science, and will assuredly lead the physicist of the future to attempt once more to grapple with those problems concerning the ultimate construction of the material world, which Descartes and Leibnitz attempted to solve, but which have been sedulously ignored by most of their successors.

One Royal Medal has been awarded to Dr. T. Archer Hirst, F.R.S., for his investigations in pure geometry; and, more particularly, for his researches into the correlation of two planes and into the complexes generated by them.

The other Royal Medal has been awarded to Dr. J. S. Burdon Sanderson, F.R.S., for the eminent services which he has rendered to physiology and pathology; and, especially, for his researches on the electrical phenomena exhibited by plants, and for his investigations into the relation of minute organisms to disease.

In making this award, the Council desire not merely to recognise the merit of Dr. Burdon Sanderson's researches, especially those on the analogy between the electrical changes which take place in the contractile tissues of plants and those which occur in the like tissues of animals; but to mark their sense of the important influence which Dr. Sanderson has exerted upon the study of physiology and pathology in this country.

The Davy Medal has this year been again awarded in duplicate, the recipient being M. Marcellin Berthelot, Member of the Institute of France, and Foreign Member of the Royal Society, and Prof. Julius Thomsen, of Copenhagen.

The thermo-chemical researches of Berthelot and Thomsen have extended over many years, and have involved an immense amount of work, partly in the application of established methods to new cases, partly in devising new methods and applying them to cases in which the older methods were not applicable. Chemists had identified a vast variety of substances, and had determined the exact composition of nearly all of them, but of the forces which held together the elements of each compound they knew but little. It was known that certain elements combine with one another with great evolution of heat-forming products in which they are firmly united; while other elements combine but feebly, and with little evolution of heat. But the materials for forming any general theory of the forces of chemical combination were but scanty and imperfect.

The labours of Messrs. Berthelot and Thomsen have done much towards supplying that want, and they will be of the utmost value for the advancement of chemical science.

THE JAVA DISASTER

THE following letter from the Liverpool *Daily Post*, received from Capt. W. J. Watson, of the British ship *Charles Bal*, contains a graphic and interesting account of the recent terrible volcanic outburst in Sunda Straits. Capt. W. J. Watson was himself an eye-witness of what he describes. His vessel was actually within the Straits, and not far from Krakatoa when that island had become an active volcano:—

'*August* 22, 15° 30′ S., 105° E.—About 7 p.m. the sea suddenly assumed a milky-white appearance, beginning to the east of us, but soon spreading all round, and lasting till 8 p.m. There were some clouds (cumulus) in the sky, but many stars shone, and in the east to north-east a strong, white haze or silvery glare. This occurred again between 9 and 10 p.m., the clouds also appearing to be edged with a pinkish coloured light, the whole sky also seeming to have extra light in it, similar to when the aurora is showing faintly. On the 24th, in 9° 30′ S. 105° E., we had a repetition of the above. On the night of the 25th, standing in for Java Head, the land was covered with thick, dark clouds and heavy lightning. On the 26th, about 9 a.m., passed Prince's Island, wind south-west, and some heavy rain; at noon, wind west-south-west, weather fine, the Island of Krakatoa to the north-east of us, but only a small portion of the north-east point, close to the water, showing; rest of the island covered with a dense black cloud. At 2.30 p.m. noticed some agitation about the Point of Krakatoa; clouds or something being propelled from the north-east point with great velocity. At 3.30 we heard above us and about the island a strange sound as of a mighty, crackling fire, or the discharge of heavy artillery at second intervals of time. At 4.15 p.m., Krakatoa north half east, ten miles distant, observed a repetition of that noted at 2.30, only much more furious and alarming, the matter, whatever it was, being propelled with amazing velocity to the north-east. To us it looked like blinding rain, and had the appearance of a furious squall of ashen hue. At once shortened sail to topsails and foresail. At five the roaring noise continued and increased; wind moderate from south south-west; darkness spread over the sky, and a hail of pumice-stone fell on us, many pieces being of considerable size and quite warm. Had to cover up the skylights to save the glass, while feet and head had to be protected with boots and southwesters. About six o'clock the fall of larger stones ceased, but there continued a steady fall of a smaller kind, most blinding to the eyes, and covering the decks to three or four inches very speedily, while an intense blackness covered the sky and land and sea. Sailed on our course until we got what we thought was a sight of Fourth Point Light; then brought ship to the wind, south-west, as we could not see any distance, and we knew not what might be in the Straits, the night being a fearful one. The blinding fall of sand and stones, the intense blackness above and around us, broken only by the incessant glare of varied kinds of lightning and the continued explosive roars of Krakatoa, made our situation a truly awful one. At 11 p.m., having stood off from the Java shore, wind strong from the south-west, the island, west-north-west, eleven miles distant, became more visible, chains of fire appearing to ascend and descend between the sky and it, while on the south west end there seemed to be a continued roll of balls of white fire; the wind, though strong, was hot and choking, sulphureous, with a smell as of burning cinders, some of the pieces falling on us being like iron cinders, and the lead from a bottom of thirty fathoms came up quite warm. From midnight to 4 a.m. (27th) wind strong, but very unsteady, between south-south-west and west-south-west, the same impenetrable darkness continuing, the roaring of Krakatoa less continuous, but more explosive in sound, the sky one second intense blackness and the next a blaze of fire, mastheads and yardarms studded with corpo-ants and a peculiar pinky flame coming from clouds which seemed to touch the mastheads and yardarms. At 6 a.m., being able to make out the Java shore, set sail, passing Fourth Point Lighthouse at 8; hoisted our signal letters, but got no answer. Passed Anjer at 8.30, name still hoisted, close enough in to make out the houses, but could see no movement of any kind; in fact, through the whole Straits we have not seen a single moving thing of any kind on sea or land. At 10.15 a.m. passed the Button Island one-half to three-quarters of a mile off; sea like glass round it, weather much finer looking, and no ash or cinders falling; wind at south-east, light. At 11.15 there was a fearful explosion in the direction of Krakatoa, now over thirty miles distant. We saw a wave rush right on to the Button Island, apparently sweeping right over the south part, and rising half way up the north and east sides. This we saw repeated twice, but the helmsman says he saw it once before we looked. The same wave seemed also to run right on to the Java shore. At the same time the sky rapidly covered in; the wind came strong from south-west by south; by 11.30 we were inclosed in a darkness that might almost be felt, and at the same time commenced a downpour of mud, sand, and I know not what; ship going north-east by north, seven knots per hour under three lower topsails; put out the side-lights, placed two men on the look-out forward, while mate and second mate looked out on either quarter, and one man employed washing the mud off binnacle glass. We had seen two vessels to the north and north-west of us before the sky closed in, adding much to the anxiety of our position. At noon the darkness was so intense that we had to grope our way about the decks, and although speaking to each other on the poop, yet could not see each other. This horrible state and downpour of mud, &c., continued until 1.30, the roarings of the volcano and lightnings being something fearful. By 2 p.m. we could see some of the yards aloft, and the fall of mud ceased. By 5 p.m. the horizon showed out in the north and north-east, and we saw West Island bearing east and north, just visible. Up to midnight the sky hung dark and heavy, a little sand falling at times, the roaring of the volcano very distinct, although in sight of the North Watcher, and fully sixty-five or seventy miles off it. Such darkness and time of it in general few would conceive, and many, I dare say, would disbelieve. The ship, from truck to water-line, is as if cemented; spars, sails, blocks, and ropes in a terrible mess; but, thank God, nobody hurt or ship damaged. On the other hand, how fares it with Anjer, Merak, and other little villages on the Java coast?"

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The Natural Science Scholarships at Christ Church have been awarded after examination to Mr. R. E. Scholefield, of Leeds Grammar School, and Mr. H. Bankes Price, of Christ's College, Brecon. The Brakenbury Natural Science Scholarship at Balliol College has been awarded to Mr. R. P. Baker, of Clifton College. The following gentlemen were distinguished in the examination:—Mr. W. H. Littleton, Royal School of Mines, Mr. T. H. J. Watts, of Llandovery School, and Mr. C. E. Rice, of Derby Grammar School.

An examination will be held on January 29 at Queen's College for the election of a scholar in Natural Science.

CAMBRIDGE.—The Special Board for Mathematics, in publishing, after the lapse of two-thirds of the present term, a list of professorial lectures on Mathematics, with a list of College lectures open to all members of the University, states that six associated Colleges, Peterhouse, Pembroke, Corpus, Queens', St. Catharine's, and Downing, provide no lectures on higher Mathematics this term, while none will be given during the year at Jesus, Trinity Hall, Magdalen, Sidney, Cavendish, and Selwyn. St. John's does not as yet open any of its advanced lectures to other than its own students. Trinity, on the contrary, has five advanced courses this term open to the University, viz. Mr. Thomson on Electrostatics and on Statics and Attractions, Mr. Ball on Higher Differential and Integral Calculus, Mr. Glazebrook on Geometrical Optics, and Mr. Glaisher on Elliptic Functions. At King's Mr. Stearn is lecturing on Electrostatics, at Christ's Mr. Hobson on Magnetism, at Clare Mr. Mollison on Fourier's Theory and Heat. Several subjects in higher Mathematics are unrepresented by lectures this year, such as Differential Equations, Calculus of Finite Differences, Calculus of Variations, Theory of Probability, Lagrange's and Bessel's Functions, Higher Dynamics, Newton's "Principia," Planetary Theory, and Precession. The Board regret that no conference of mathematical lecturers has been held, and that there is no uniformity of procedure between the different Colleges. In all the other chief departments of study, programmes of advanced lectures for the whole year were published last June. It is somewhat of a reproach to Cambridge mathematicians that no such list is published in regard to what was once so distinctively the characteristic study of Cambridge.

The following are the examiners for the Natural Sciences Tripos of 1884:—Prof. A. M. Marshall (zoology), Dr. F. Darwin (botany), Mr. Langley (physiology), Dr. R. D. Roberts (geology), Mr. L. Fletcher (mineralogy), Mr. W. N. Shaw (physics), Mr. A. Hill (human anatomy), Mr. Pattison Muir (chemistry).

The recommendations of the General Board of Studies as to the Professor of Pathology, new readers, University lecturers, demonstrators, grants for apparatus, &c., will be voted on December 6 at noon.

Prof. Foster has been appointed on the University Library Syndicate; Prof. Foster and Dr. Vines, the Botanic Garden Syndicate; Revs. Coutts Trotter and E. Hill, the Museums and Lecture Rooms Syndicate; Messrs. H. Darwin and J. J. Thomson, the Observatory Syndicate; Prof. Cayley, the University Press Syndicate; Dr. Gaskell and Mr. A. S. Lea, the Oxford and Cambridge Examinations Syndicate; Prof. Foster, the State Medicine Syndicate; Prof. Stuart and Mr. J. Ward, the Teachers' Training Syndicate.

The following appointments on Special Boards have been made:—Mr. A. S. Lea (medicine), Dr. Ferrers (mathematics), Prof. Stokes (physics and chemistry), Mr. J. E. Marr (biology and geology).

Prof. Macalister has been appointed Examiner in the 2nd M.B. in place of the late Mr. James Shuter.

Mr. W. Gardiner of Clare College has been approved as a Teacher of Botany for the purposes of medical study.

SCIENTIFIC SERIALS

THE *Journal of Anatomy and Physiology*, vol. xviii. part 1, October, 1883, contains:—On the development of the suspensory ligament of the fetlock in the fœtal horse, ox, roe deer, and sambar deer, by Prof. Dr. J. Cunningham, M.D. (plate 1).—On the action of infused beverages on peptic digestion, by Dr. J. W. Frazer (plate 2).—On a method of promoting maceration for anatomical museums by artificial temperature, by Prof. Struthers, M.D.—On the wax-like disease of the heart, by Prof. D. J. Hamilton, M.D. (plate 3).—On the relations of the dorsal artery of the foot to the cuneiform bones, by A. Hensman.—Researches into the histology of the central gray substance of the spinal cord and medulla oblongata, by Dr. W. Ainslie Hollis, part 2 (plate 4).—On some points in the anatomy of the chimpanzee, by J. B. Sutton.—Observations upon the osteology of *Podasocys montanus*, by Dr. R. W. Shufeldt (plate 5).—Short notes on the myology of the American black bear, by Prof. F. J. Shepherd, M.D.—Total absence of the left lobe of the thyroid body, by Dr. W. J. Gow.—Note respecting the course of the flexor longus digitorum pedis, by Dr. Sinclair White.—On the os centrale in the human carpus, by Prof. W. Gruber.

THE *Quarterly Journal of Microscopical Science* for October, 1883, contains:—Observations on the genus Pythium, by H. Marshall Ward, M.A. (plates 34 to 36).—On budding in Polyzoa, by Prof. A. C. Haddon, M.A. (plates 37, 38).—On the structure and relations of Tubipora, by Sydney J. Hickson, B.A., B.Sc. (plates 39, 40).—On the malleus of the Lacertilia and the malar and quadrate bones of the mammalia, by M. L. Dollo (plate 41).—Notes on Echinoderm morphology, No. 6; on the anatomical relations of the water-vascular system, by P. Herbert Carpenter, M.A.—Recent researches upon the origin of the sexual cells in hydroids, review by A. G. Bourne, B.Sc.—On the osteology and development of *Syngnathus peckianus* (Storer), by J. Playfair McMurrich, M.A. (plates 42, 43).

THE *American Journal of Science*, November, 1883.—Results of some months' examination of the spectra of sunspots with an instrument of high dispersion, by Prof. C. A. Young.—On the meteoric iron mass found by F. M. Anderson near Dalton, Whitfield County, Georgia, in 1879 (two illustrations), by Charles Upham Shepard, sen. The analysis gave iron 94·66, nickel 4·80, cobalt 0·34, with traces of phosphorus, chromium, and manganese.—Notice of some varieties of corundum recently found at Sungchang, Zanskar district, Western Himalayas, by the same author.—Phenomena of the Glacial and Champlain periods about the mouth of the Connecticut Valley, that is, in the New Haven region (two maps), by James D. Dana. The author concludes that two simultaneous movements existed in the glacier ice—a lower along the valley, an upper crossing it obliquely; that both transported drift material, and that on reaching Long Island Sound the lower changed its own direction of flow for that of the general glacier mass across the Sound and Long Island.—On a variety of descloizite from Zacatecas, Mexico, by Samuel L. Penfield.—On Hybocrinus, Hoplocrinus, and Bærocrinus (two illustrations), by Charles Wachsmuth and Frank Springer.—Note on Mr. Nipher's papers on the evolution of the American trotting horse (one illustration), by W. H. Pickering. The author holds that we may foretell the speed attained for a few years in advance, but not the ultimate speed, nor when it will be reached.—On the discovery of Utica slate graptolites on the west side of the Hudson River, a few miles north of Poughkeepsie, by Henry Booth.—On Becraft's Mountain, near Hudson, Columbia County, New York (one illustration), by William Morris Davis. After describing the district formations, and their relative and absolute positions, the author deals with the question of nonconformity between the Lower and Upper Silurian systems of the locality and the relations of these systems elsewhere. In another communication he discusses the question of nonconformity at Rondout, New York.—Notice of agricultural, botanical, and chemical results of experiments on the mixed herbage of permanent meadows, conducted for more than twenty years in succession on the same land, by D. P. Penhallow. The results are tabulated, and are valuable as showing the influence of different fertilisers upon the character of vegetation and the total produce.—Note on Mr. Backhouse's observations on physiological optics, by W. Le Conte Stevens.

Bulletin of the Belgian Académie Royale des Sciences, des Lettres, et des Beaux Arts, August 5, 1883.—Report on M. Gravis' anatomical researches on the vegetative organs and structure of the *Urtica dioica*, by MM. Ed. Morren and Gilkinet.—Report on M. Paul Albrecht's work on the pelvisternum of the Edentates, by MM. P. J. Van Beneden and Van Bambeke.—Note on a thunderbolt which fell near Gougnies on July 11, 1868, by M. D. Van Bastelaer.—Report on M. Delaey's steam engine of universal application, by M. Maus.—Remarks on some new fossils found in the Belgian Tertiary formations, by M. P. J. Van Beneden.—Note read to the Academy on presenting the two first parts of his work on the theory of the diurnal, annual, and secular movements of the axis of the globe, by M. F. Folie.—Observations on a recent note by M. P. J. Van Beneden, touching the discovery of the Bernissart fossil iguanodons, by M. E. Dupont.—Note on the influence of respiration on blood-pressure, by MM. Em. Legros and M. Griffé.—Report on M. G. Tiberghien's philosophic dissertation on time, by M. A. Le Roy.—Note on M. de Sonnaz's historical studies on the county of Savoy, by M. Rivier.—Communication on some autographs of Grétry, by M. Stanislas Bormans.

Archives Italiennes de Biologie, tome iv. fasc. 1, October 31, 1883, contains:—On the zoological station at Naples, by C. Emery.—On le charbon in birds, by E. Perroncito.—On a true diffused kidney in certain mollusca, by S. Trinchese.—On the optic lobes of birds, by J. Bellonci.—On the oscillations of the typhoid fever epidemic at Paris in connection with the rainfall and sewage of that city, by L. Pagliani.—On paraldehyde as antagonistic to strychnine, by V. Cervello.—On the active properties of *Nigella sativa*, by P. Pellacani.—On the genesis of Ptomaines, by F. Coppola.—Researches as to the poison of *Triton cristatus*, by A. Capparelli.—Embryological researches as to the mammalian kidney, by C. Emery.—Histological researches as to the nervous centres, by C. Golgi.—Obituary notices of P. Pacini, N. A. Pedicino, and Victor Colomiatti.

Zeitschrift für wissenschaftliche Zoologie, Bd. xxxix., Heft 1, September 28, 1883, contains:—Researches on the interstitial connective tissue in mollusca, by Dr. J. Brock (plates 1 to 4).—On the germinal layers of the tail end of *Lumbriculus variegatus*, with a contribution to the anatomy and history of this worm, by Dr. C. Bulow (plate 5).—On the histogenesis of the bones in Teleostei, by Carl Schmid-Monnard (plates 6 to 9).—Remarks concerning the blood lacunæ and the connective tissue in Najadæ and Mytilidæ, by W. Flemming.—Contributions to the histology of the Echinoderms, No. 1, the Holothuria (Pedata) and the nervous system of the Asteridæ, by Dr. Otto Hamann (plates 10 to 12).

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, November 15.—Sir John Lubbock, Bart., F.R.S., president, in the chair.—Messrs. Philip Crowley and J. Murray were elected Fellows of the Society.—Mr. Charles B. Plowright exhibited a young pear tree showing *Rœstelia cancellata*, Jacq., produced from *Podisoma sabinæ*, therefore supporting the observations of A. S. Œrsted in *Botaniska Notiser* for 1865; also examples of *Puccinia graminis* on wheat produced from Œcidium on *Mahonia aquifolia*; the Œcidiospores were sown June 2, 1883, the Uredospores were sown June 10, and the ripe *P. graminis* was gathered September 10, 1883. He likewise called attention to examples of *Œcidium rumicis* on *Rumex obtusifolius*, *R. hydrolapathum*, *R. conglomeratus*, and *Rheum officinale*, the same being produced from *Puccinia phragmitis*.—Prof. P. Martin Duncan showed a specimen of coral (*Desmophyllum crista-galli*) which had grown upon an electric telegraph cable off the shores of Spain; it possessed radicles, apparently due to the presence of a worm close beneath the base of the coral.—Mr. E. P. Ramsay exhibited a series of rare New Guinea birds, and Mr. R. B. Sharpe made remarks thereon.—Mr. T. Christy exhibited a fine living and healthy specimen of *Trevesia sundaica*, Miq. (the so-called *Gastonia palmata*), or probably a new species. This peculiar and handsome plant has rarely been seen in this country, and of late years almost been lost sight of.—Dr. J. Murie showed and made remarks on specimens of *Ascaris bicolor* from the living walrus at the Westminster Aquarium.—Mr. F. I. Warner drew attention to a series of specimens of *Orchis incarnata* from Hampshire.—A paper was read by Mr. A. W. Bennett, on the reproduction of the Zygnemaceæ, as a solution of the question, Is it a sexual character? De Bary twenty-five years ago, and since then Wittrock, have instanced what they have deemed sexual differences between the conjugating cells, though most later writers rather ignore essential physiological distinctions. Mr. Bennett has directed his investigations chiefly to the genera *Spirogyra* and *Zygnema*, and from these he supports the inference of the abovementioned authors. He finds there is an appreciable difference of length and diameter in the conjugating cells, that deemed the female being the larger. The protoplasmic contents he also finds pass only in one direction, and change first commences in the chlorophyll bands of the supposed male cells, with accompanying contraction of the protoplasmic material. The genera *Mesocarpus*, *Staurospermum*, and the doubtful form *Craterospermum* have likewise been examined, and, though showing differences, yet on the whole substantiate the view above enunciated of cell sexuality.—There followed the reading of notes on the antennæ of the honey bee, by Mr. T. J. Briant, in which he describes the minute structure of the segments, the joints and certain rod and cone like organs, previously referred to by Dr. Braxton Hicks, of highly sensitive function.—A paper was read on the Japanese Languriidæ, their habits and external sexual characteristics, by Mr. G. Lewis. He remarks that a representative of the family has been found in Siberia, lat. 46° (*L. menetriesi*); there are none in Europe, and one is known from Egypt. Others inhabit the Malay Archipelago, Ceylon, and the American continent. The author infers from the geographical distribution of these beetles that they have emanated from a tropical area. Some in the imago state cling to the stems of brushwood; others sit on the leaves of the moist shade-loving plants in the forests, while still others frequent debris on hill sides. Their colours are all dull, their bodies elongate and not structurally adapted for boring. The sexes show peculiar differences in size, and monstrous enlargement and obliquity of the head, volume of tibia, &c.—A paper was read by Prof. P. Martin Duncan on the replacement of a true wall or theca by epitheca in some Serial Coralla, and on the importance of the structure in the growth of incrusting corals. After alluding to the discussions which have taken place regarding the value of epitheca in classification, the author states that one form of this structure is simply protective, and that another form is of high physiological value, for it replaces entirely the usual theca or wall. The anatomy of the hard structures of a Cœloria illustrates the second proposition, for the broad base is covered by an epitheca, within which is no wall or "plateau commun," the septa, remarkable nodular walls (described in detail), and the columellæ arise from the epitheca directly, and it limits the interseptal loculi inferiorly. In a Leptoria the the same replacement of a wall by epitheca is seen. In incrusting Porites and such Astræidæ as Leptastræa the majority of the corallites of the colony arise from this basal epithecate structure, and grow upwards, budding subsequently from their sides.

Royal Meteorological Society, November 21.—Mr. J. K. Laughton, F.R.A.S., president, in the chair.—The Earl of Dalhousie, K.T., T. H. Davis, D. C. Embleton, J. Hargreaves, and J. L. Lewington were elected Fellows of the Society.—The following papers were read:—Report on temperatures in two different patterns of Stevenson screens, by E. Mawley, F.R.Met.Soc. The screens employed were an ordinary Stevenson screen obtained from Casella, and a new Stevenson screen made in accordance with the recommendations of a committee appointed by the Council of the Society. The new screen is two inches wider and deeper than the old screen. It has also an upper sloping roof, and, at a little distance below, a flat, inner roof pierced with holes for ventilation; while the old screen has a single flat roof with only a narrow slit beneath on each side for ventilation. Observations were made during the three months July to September, and the results are given in the paper. From these it appears that the new screen is, of the two, slightly cooler and better ventilated, and retains the heat of the sun for a less time than the old screen; also, having a double roof and overlapping boards below, it is bettter suited for extreme climates.—On the storm which crossed the British Isles between September 1 and 3, 1883, and its track over the North Atlantic, by C. Harding, F.R.Met.Soc., of the Meteorological Office. This storm caused considerable havoc in the south-west and south of England, owing not only to its exceptional violence, but also to its occurrence before the completion of the harvest. The storm is traceable, in the first instance, to two centres of disturbance, one being first shown at about 450 miles to the south of Bermuda on August 26, and the other to the east of the Rocky Mountains on the 27th; these two disturbances afterwards merged on the 29th, at about 300 miles to the north of Bermuda, and formed one great and destructive gale, which continued to grow in violence as it crossed the Atlantic until it reached the coasts of the British Islands. The average speed at which this storm crossed the Atlantic was fully forty miles an hour, which is more than double the usual speed of storms which traverse that ocean.—On the influence of the moon on the height of the barometer within the tropics, by Robert Lawson, Inspector-General of Hospitals.—The great ice-storm of July 3, 1883, in North Lincolnshire, by J. Cordeaux. The direction of the storm was nearly south-east to north-west, and travelled from Caistor along the higher ridges of the hills to Barton-on-Humber. The storm commenced at about 9.20 p.m. with heavy drops of rain, and increased to a downpour, speedily followed, amidst the blaze of lightning and the constant roll of thunder, by the rush of hail, or rather lumps of ice. An eye witness remarked that they were not like hailstones, but "salt-cellars"; another that they resembled "ducks' eggs"; in fact they were solid lumps of ice of every shape and size, weighing from two to six ounces, and some were measured six inches in circumference. The injury done to the growing crops cannot be estimated at less than 20,000*l*.

Physical Society, November 24.—Prof. R. B. Clifton in the chair.—Prof. Reinold read a paper by Mr. J. W. Clark, on the purification of mercury by distillation in vacuo. The advantages of Mr. Clark's apparatus are—the small quantity of mercury in use at a time, and the fact that no auxiliary Sprengel pump is required. This is avoided by having a movable reservoir of mercury, on raising which the distiller is filled with mercury. The apparatus was described in detail, and illustrated by a figure. It is probable that zinc, cadmium, magnesium, &c., may be distilled and thus purified by the same apparatus.—Mr. A. P. Chattock then read a paper on a method of determining experimentally the constant of an electrodynamometer. In existing methods it is necessary to measure the areas of the coils, which is a difficult matter to do with a finished instrument; by the new method this is unnecessary. It depends on the accurate determination of the speed of the movable coil. Mr. Chattock exhibited an instrument whose constant had been determined by him in the laboratory of Prof. Foster, University College, with the assistance of Mr. Grant.—Prof. G. C. Foster then took the chair, and Prof. R. B. Clifton, president, read a paper on the measurement of the curvature of lenses. With very small lenses the spherometer cannot be used, and the author's method is based on the Newton's rings formed between the lens and a plane surface, or a curved surface of known radius. From the wave-length of the light employed in observing, and the diameter of a ring, the radius of curvature can be determined. He places the lens on a plane or curved surface under a microscope, and lights it by the sodium flame (wave-length 5892×10^{-7}); he measures the approximate diameters of two rings a distance apart (in practice the tenth and twentieth rings are found convenient), takes the difference of their squares, and divides it by the wave-length, and the number of rings in the gap between to find the radius of the lens. The formula is—

$$\rho^1 m \lambda = \left(x^2_{m+n} - x^2_n\right)$$

where x_{m+n} and x_n are the diameters of the *m*th and $(m+n)$th rings; λ is the wave-length of the light, and ρ^1 the radius of curvature of the lens. The method with proper care gives accurate results. Prof. Clifton has also used it to determine the refractive index of liquids in small quantities; Mr. Richardson having found it for water = 1·3335 by this method, which is usually correct to two places of decimals. It can also be used to determine if the lens is uniformly curved and spherical. Prof. Perry suggested that it might be also used to measure a surface without touching it, say the surface of a water drop, or a strip of glass when bent. In this way it might throw light on the laws of capillarity or bending.

MANCHESTER

Literary and Philosophical Society, October 2.—H. E. Roscoe, F.R.S., president, in the chair.—On the change produced in the motion of an oscillating rod by a heavy ring surrounding it, and attached to it by elastic cords, by James Bottomley, F.C.S.

October 16.—H. E. Roscoe, F.R.S., president, in the chair.—On the leaves of *Catha edulis*, by C. Schorlemmer, F.R.S.—Dr. Schuster, F.R.S., gave an account of meteoric dust, and exhibited some specimens found in Himalayan snow.—On the duality of physical forces, by James Rhodes, M.R.C.S.

October 30.—J. P. Joule, F.R.S., vice-president, in the chair.—On the action of water upon beds of rock salt, by Thomas Ward.

CAMBRIDGE

Philosophical Society, October 29.—On the structure of the cells of secretory glands, by Mr. J. W. Langley.—Note on the fibrin-ferment, by Messrs. A. S. Lea and J. R. Green.—On the structure of the epidermis of the ice-plant (*Mesembryanthemum crystallinum*), by Mr. M. C. Potter.—On the physiological significance of water-glands, by Mr. Walter Gardiner.

PARIS

Academy of Sciences, November 26.—M. Blanchard, president, in the chair.—On the treatment of plague-stricken swine by vaccination with the fatal virus itself in an attenuated form, by M. Pasteur and the late M Thuillier.—On the hydratation of crotonic aldehyde, by M. Ad. Wurtz.—Propagation across the Indian and Atlantic Oceans of the great earthquake wave caused by the recent disturbances at Java, by M. de Lesseps. From the observations taken at Colon by the engineers engaged on the Panama Interoceanic Canal, the wave would appear to have made its way in about thirty hours from Java, round the Cape of Good Hope to the east coast of Central America.—Theoretical considerations on the action of floats kept in tow at divergent angles, by M. E. de Jonquières.—On the secular variation in the direction of the terrestrial magnetic force at Paris, by M. L. Descroix.—On the successive parthenogenetic reproduction of phylloxera for nine generations, and on the results obtained by various methods of treatment of vines attacked by phylloxera made by M. P. Boiteau.—Observations of the planets 233 and 234 at the Paris Observatory (equatorial of the west tower), by M. G. Bigourdan.—On a formula of M. Tisserand connected by the celestial mechanism, by M. O. Callandreau.—On the algebraic integration of linear equations, by M. H. Poincaré.—On an induction magnetic needle, by M. Mascart.—On the electric synchronism of two relative movements, and its application to the construction of a new electric compass, by M. Marcel Deprez.—A study of earth currents, by M. E. E. Blavier.—Measurement of the differences of potential of electric layers on the surface of two liquids in contact (four illustrations), by MM. E. Bichat and R Blondlot.—Wave-lengths of the optical rays A and *a*, by M. W. de W. Abney.—Description of a microthermometer for gauging very slight variations of temperature, by M. F. Larroque.—Studies on the chemical action of light; decomposition of oxalic acid by the perchloride of iron (three illustrations), by M. G. Lemoine.—Dissociation of the anhydrous carbonate of ammonia caused by excess in one or other of its elements, by M. Isambert.—On the fusibility of salts; nitrates, by M. E. Maumené.—On hydronicotine and oxytrinicotine, by M. A. Étard.—On the relative velocity of the sensations of sight, hearing, and touch, by M. A. Bloch. This paper consists of three distinct parts, each dealing with the comparison of two sensations—(1) hearing and touch; (2) hearing and sight; (3) sight and touch. The author concludes that of the three sensations sight is the most rapid; then hearing, the transmission of which sensation lasts 1/72 of a second longer than that of sight; lastly, touch, the transmission of which takes 1/21 of a second more than sight.—On the nervous system and the classification of the Phyllodoceæ, a hitherto little-studied family of Annelidæ, by M. G. Pruvot.—On the axis of *Œnanthus crocata* and *fistulosa*, and on abnormal vegetable productions in general, by M. R. Gérard.—On the propagation of the earthquake waves caused by the late volcanic eruption at Java, by M. Bouquet de la Grye.—A contribution to the volcanic theory, by M. Stan. Meunier.

BERLIN

Physiological Society, November 9.—Dr. Friedländer two years ago had communicated to the Society how in eight different cases of genuine croupous pneumonia, which ended fatally on the disease reaching its height, he had constantly found in the lungs a micrococcus, mostly in the form of diplococcus, which seemed to be a characteristic of genuine pneumonia. Since then the cases of croupous pneumonia he had examined amounted to over fifty, and with but very few exceptions the same description of cocci had been found in all the lungs affected. The few cases in which pneumonic cocci failed to show themselves were regularly such in which death had set in after the eighth day of the disease, that is after the disease had finished its course. In all other kinds of pneumonia, such, for example, as follow in the train of typhus, or attack old persons, &c., diplococci did not appear. It was beyond doubt, therefore, that they were a characteristic of genuine croupous pneumonia alone. That micrococci had not been perceived by many observers in the case of genuine pneumonia was owing to the fact that it was difficult to make them visible in the tissues; for only when they were highly coloured while the surrounding tissue remained colourless did they become distinctly visible. To render them apparent it was of advantage to colour thin sections of the lungs with methylic-violet or gentian-blue, and then to apply a diluted solution of iodine by means of which the tissues which were at first also coloured would become clear and so bring out the strongly-coloured cocci. Quite recently two cases had been published in which pneumonic cocci had been found *intra vitam*—one case by Prof. Leyden, the other by Dr. Günther. The latter observer invariably found the cocci inclosed in a pale and sharply-defined envelope, which, on the application of colouring-matter, likewise became highly coloured. Cocci having in both the cases referred to been obtained by means of puncture, and thus their presence in the fluid of the lungs demonstrated, Dr. Friedländer set himself also to examine the fluid of the lungs in the bodies of persons who had died from pneumonia, and found there large quantities of pneumonic cocci, which were particularly well adapted for examination, being in a free state. He was now in a position to prove that they all possessed envelopes, which, by their reactions (they came out most distinctly on being subjected to acids, and disappeared under distilled water or an alkali), appeared to consist of mucin, and to be very essential to the life and activity of the cocci. According to the experience acquired down to the present date, the pneumonic cocci were the only ones which possessed this kind of slimy capsule. The problem now presented was, by means of experiments in the way of cultivation and inoculation, to determine the distinguishing characteristics and the pathogenic nature of these cocci. This task Dr. Friedländer, in conjunction with Dr. Frobenius, had undertaken with positive results. According to the methods of Prof. Koch, the cocci taken from the lungs of persons who had died from genuine pneumonia were disseminated on stiffened gelatine (consisting of gelatine, an infusion of flesh and common salt). From these proceeded invariably and in all generations perfectly characteristic organisms distinguished from all other fungous products of cultivation by their peculiar nail-like shape. No other kind of micro-organism showed the same nail-like form under cultivation as did that taken from persons pneumonically affected who had died on the disease reaching its acme, and whose lungs were afterwards examined; nor did any other species of pneumonia ever yield this form of cultivated organism. Experiments in the way of inoculation had been made on mice, guinea-pigs, rabbits, and dogs. The mice were subjected to injections either of cultivated cocci which had been obtained by dissemination of fresh lung-fluid containing cocci. Almost all these mice died after twenty to twenty-eight hours, under symptoms of violent dyspnœa; and on a section being made, extensive pleurisy and pneumonia were observed in each case; in the blood, likewise, diplococci were found to be very abundant, as also in the pleural exudations and in the tissues of the lungs. Were the cocci thus found disseminated on gelatine, they then yielded the nail-like cultivated organisms already referred to, exactly in the same way as did the cocci of genuine pneumonia in the case of man. Were again these cultivated cocci injected into other mice, these mice died of pneumonia on the second day after the inoculation. If, however, the fluid containing cocci were heated to about 70° C. before being injected into the mice, it was thereby rendered inefficacious, and the mice received no harm from it. On the pleural cavity of the mice being examined, many cocci were indeed still found in the fluid, but when these were strewn on gelatine they either remained sterile or developed other than the nail-like cultivated organisms. Not only, however, by injection of pneumonic cocci through Pravaz's syringe could pneumonia be produced in mice, but likewise also by means of inhalation. If mice, shut up in a chest, were compelled to breathe an atmosphere saturated by means of a spray with pneumonic cocci, then did a number of the mice die under the same symptoms as followed injection, though in this case not till the fourth or fifth day after the operation; the blood in the lungs of those mice who had died from experimental genuine pneumonia also contained characteristic pneumonic cocci. The results obtained from analogous experiments in inoculation with guinea-pigs were less decisive. About a half of the guinea-pigs inoculated by means of injection of pneumonic cocci remained in a perfectly healthy state, showing that they were proof against cocci. The other half, however, perished of dyspnœa, and their blood, lungs, and pleural exudations were found to contain double micrococci, which being sown on gelatine produced the characteristic nail-like organisms, and on being injected gave rise to pneumonia in the creatures so inoculated. The same experiments were next tried on five dogs. Four of them remained unscathed, but one sickened and died of dyspnœa. On a postmortem being made, this last dog showed symptoms of pneumonia and the presence of the characteristic diplococci in its blood and lungs. In the four healthy dogs, on the other hand, the injected cocci had all suffered destruction. In the case of the rabbits the experiments in inoculation were wholly without effect. They showed themselves completely proof against pneumonic cocci, and the cocci injected into their lungs were, after a few days, no longer traceable. From the invariable discovery of diplococci in the lungs of bodies that had died of genuine pneumonia before the disease had run its full course, and from the experiments with cultivated cocci, as also by inoculation of mice, Dr. Friedländer drew the conclusion that the cocci found by him were the cause of the genuine croupous pneumonia which had also before been recognised as infectious. On a future occasion Dr. Friedländer will again take up this subject, so important both from a scientific and a practical point of view.

PROFESSOR STOKES' WORKS

Mathematical and Physical Papers. By G. G. Stokes. (Cambridge University Press. Vol. I., 1880; Vol. II., 1883.)

THIS is the age of Reprints of the works of great living men, even in an hourly growing subject like Science. The pseudo-scientists have long been accustomed to galvanize into life again, for a few brief moments, their defunct prelections by collecting them in a volume with some catching title. But the real men of science are now building, during their life-time, each his *monumentum ære perennius, regalique situ Pyramidum altius.* Von Helmholtz and Kirchhoff have collected and reissued their scattered masterpieces. Clausius has joined one large series of his works into a connected treatise. At home Sir W. Thomson has given us a grand collection, *Electrostatics and Magnetism,* and the rest of his papers are to appear in a series of volumes, of which one is already before the public. But, heartily as we welcome all these splendid volumes, here is something at least as good as the best of them, and *much more imperatively required.*

There can be but one opinion as to the value of the collection before us, and (sad to say) also as to the absolute *necessity* for it. The Author, by common consent of all entitled to judge, takes front rank among living scientific men as experimenter as well as mathematician. But the greater part of his best work has hitherto been buried in the almost inaccessible volumes of the *Cambridge Philosophical Transactions,* in company with many other papers which deserve a much wider circulation than they have yet obtained. Stokes' well-deserved fame was thus practically secured by means of a mere fraction of his best work. And another inconvenience, which will *now* have some chance of being repaired, has arisen from the same cause. Science demands, at every instant, the solution of certain definite problems each suggested by the last-preceding advances:—and hosts of eager votaries are at work upon them. What is done as it were in a corner is thus sure to be done again:—done, even if not so well done; and this at the expense of unnecessary labour on the part of the second worker, who thus obtains the (temporary) award of the whole credit; while the entire process tends to the retardation of scientific progress.

The present publication will effect a very remarkable amount of transference of credit to the real author, from those who (without the possibility of suspicion of *mala fides*) are at present all but universally regarded as having won it. Two or three years ago, only, the subject for a Prize Essay in a Continental scientific society was *The nature of unpolarized, as distinguished from polarized, light.* But, all that science is even yet in a position to say, on this extremely curious subject, had been said by Stokes *thirty years ago* in the *Cambridge Philosophical Transactions.*

The malady, though grave, is simple, the cure easy. Every Society, whose Memoirs are worthy of appearing in print, ought to consider itself bound to disseminate them as widely as possible. Every University, every public library of any importance, alike in Europe and in America, should be regarded as a centre for such a purpose. The cost of the necessary additional copies should be regarded by a Society as a trifle compared with the priceless advantage of *placing* its own publications where they will be freely accessible to all who care to consult them.

And this altogether independent of the question of *exchange,* which can hardly be expected from a University, but which, in our own experience, is gladly (even eagerly) granted by almost every scientific Society worthy of the name.

Physical and Mathematical researches are the best record of the living intellectual progress of the day, and ought not to be made artificially scarce or dear. It is mere pandering to wealth and vanity which is displayed in advertisements such as "Impression strictly limited to 65 (numbered) copies. After these are printed, the type will be broken up (in presence of witnesses) and the plates destroyed."

Such advertisements are possible only in a world in which Sir Gorgius Midas, and others who have "struck ile," are the willing victims of those who prey on their selfishness, luxury, and ignorance. Education will, it is to be hoped, in time do away with such things.

To give anything like an adequate account of even one of the longer papers in these two volumes would require an entire article. And, when written, the account would in most cases be practically unintelligible to the general reader; while quite unnecessary for the student, who will of course prefer to repair to the fountain-head itself, now at last rendered easy of access.

Prof. Stokes has wisely chosen the chronological order, in arranging the contents of the volumes. Such a course involves, now and then, a little inconvenience to the reader; but this is much more than compensated for by the insight gained into the working of an original mind, which seems all along to have preferred a bold attack upon each more pressing scientific difficulty of the present, to attempts at smoothing the beginner's road into regions already well explored. When, however, Prof. Stokes does write an elementary article, he does it admirably. Witness his *Notes on Hydrodynamics,* especially that entitled *On Waves.*

Before that article appeared, an article as comprehensive as it is lucid, the subject was almost a forbidden one even to the best student, unless he were qualified to attack the formidable works of Laplace and Airy, or the still more formidable memoirs of Cauchy and Poisson. Here he finds at least the main points of this beautiful theory, disencumbered of all unnecessary complications, and put in a form intelligible to all who have acquired any right to meddle with it. It is quite impossible to tell how much real good may be done by even *one* article like this. Would there were more such! There are few, even of the most gifted men, who do not occasionally require extraneous assistance after the earlier stages of their progress:—all are the better for it, even in their maturer years.

The contents of these two volumes consist mainly, almost exclusively, of papers connected with the *Undulatory Theory of Light* or with *Hydrodynamics.* On the former subject at least, Stokes stands, without a living rival, the great authority. From the *Aberration of Light*, the *Constitution of the Luminiferous Ether*, the full explanation of the singular difficulties presented by *Newton's Rings*, to the grand theoretical and experimental treatise on the *Dynamical Theory of Diffraction*, we have a series of contributions to this branch of optics which, even allowing for improved modern surroundings, will bear comparison with the very best work of Newton, Huyghens, Young, or Fresnel in the same department.

Specially remarkable among the Hydrodynamical papers is that on *Oscillatory Waves*, to which a very important addition has been made in the reprint. The investigation of the "profile" of such a wave is here carried to a degree of approximation never before attempted.

Besides these *classes* of papers we have the very valuable treatise on *Friction of Fluids in Motion, and on the Equilibrium and Motion of Elastic Solids*. This was Stokes' early masterpiece, and it may truly be said to have revolutionized our knowledge on the subjects it treats. To mention only one point, though an exceedingly important one, it was here that for the first time was clearly shown the error of assuming any *necessary* relation between the rigidity and the compressibility of an elastic solid, such as had been arrived at from various points of view by the great Continental mathematicians of the earlier part of the present century.

Of the few purely mathematical papers in the present volumes the most important is the well-known examination of the *Critical Values of the Sums of Periodic Series*, a subject constantly forced on the physicist whenever he has to treat a case of discontinuity.

We need not say that the printing of these volumes is all that could be desired: the name of the Pitt Press is a sufficient guarantee. But the introduction, for the first time, of a *solidus* to save "spacing" and space in the printing of mathematical formulæ, was a bold step on the part of Prof. Stokes:—since amply justified by the testimony of the readers of the first of these volumes, and still more by its almost immediate adoption by thoroughly scientific as well as practical men, such as the Editors of what we still feel inclined to call by the well-known name of *Poggendorff's Annalen*.

P. G. TAIT

ROYAL ENGINEER PROFESSIONAL PAPERS

Professional Papers of the Corps of Royal Engineers. Edited by Major R. H. Vetch, R.E. Vol. VIII. 1882, 214 pp., 39 pl. (London: Stanford, 1883.)

SO many essays were contributed to these papers in 1882 that it was found necessary to publish two volumes for that year. This is a healthy sign of the interest taken by the Corps as a whole in their profession. Vol. VII. was devoted entirely to permanent fortification, a purely professional subject; whilst Vol. VIII. contains eleven papers, several of which are of general interest. This volume must have been an expensive one to get up, as it contains thirty-nine plates, some of them pretty large: the size and expense of the volume might have been considerably reduced if the contributors had prepared their plates in a more convenient shape; *e.g.* one plate, a mere genealogical table, and not really a large one (Appendix I.), has eight cross folds and one longitudinal one; this could easily have been much compressed.

Paper 3 is a careful and well got up study of the "Campaigns of Lord Lake against the Marattas," 1804-6 (9[illegible] pp., with nine plates), which will be read with interest by all students of military campaigns. A good illustration of the difficulty of ascertaining the truth abcut events of eighty years back occurs in the verification of the site of the "battle of Delhi" (1803); the supposed site is actually marked by a pillar with inscription; but, after careful collation of contemporary surveys and reports of marches, the author decides *against the site marked by the pillar*.

Paper 8 is an interesting account of the "Triangulation of Northern Afghanistan" carried out during the late war. It is worth notice here that the introduction of the heliograph into army signalling has thrown a difficulty in the way of the use of the heliotrope for survey (in the field), from the liability of confusing the signals; but there seems little doubt that in the future the army heliograph stations could be used for the survey, and be an assistance instead of a hindrance to the survey. The general result of the altitude observations has been to throw doubt on the efficiency of the aneroid, a result much to be regretted. The refraction, which in India is about ·067 of the contained arc, was found to amount to ·08 of the same in the Afghan hills; an unusual result, as refraction commonly decreases with altitude.

An interesting paper (No. 9), on "Organic Compounds in the Sun," by Capt. Abney (read in 1881), gives a popular *résumé* of the subject (up to 1881), ending with the author's spectroscopic researches showing the presence of hydrocarbons in the sun and probably in space itself; this last raises curious questions as to the constitution of the ether; can space be really full of hydrocarbons? This paper has suffered rather by the delay in publication.

Perhaps the most important (military) paper is No. 10, on "Railways for Military Communications in the Field." The author shows that the early attempts at introducing railways on field service all failed to be of much practical use from their unsuitability to the conditions, the first of which is lightness and portability of both rails and rolling-stock, and it is just herein that the English railways fail most, being amongst the heaviest in the world. A light railway largely used in the United States, which has been laid at the rate of four miles a day, is favourably mentioned. After recapitulating the various schemes which have been tried or proposed, the author gives his conclusions as to the conditions for a military railway; among the most important of these are that the gauge should be 2½ feet, the rails 10 lbs. per foot, and the line double. It is clearly impossible for any country to keep a *large* stock of railway plant specially for service: now it so happens that this 2½-foot gauge is already in use to some extent in Europe, so that the requisite plant could probably be obtained at short notice in Europe. In India, however, the metre-gauge is so largely in use that field railways in or near India will probably for many years perforce be of metre-gauge. The field railway laid for the use of the British army in South Afgahnistan (1[illegible]-80) is not mentioned; this railway was laid for a great length through a desert in hot weather at the rate of a mile a day.

The other papers in this volume are: No. 1, on "Provisional Fortification," a study of defensive works erected in a moderate time, and capable of extension and improvement, with examples from Adrianople and Tschataldscha. Paper 2, on "Graduated Arcs for Heavy Guns," contains an investigation of the errors in such arcs, and the mode of laying guns correctly, in spite of such errors. Papers 4 and 5 describe some blasting operations in Bermuda. Paper 6 describes bridges laid over the Cabul River during the war in 1879-80. Paper 7 is on "Railway Curves"; and Paper 11 contains "Tables of Ordnance Equipment." ALLAN CUNNINGHAM

OUR BOOK SHELF

Report on the Dyes and Tans of Bengal. By Hugh W. M'Cann. (Calcutta, 1883.)

THIS Report, which is issued under the direction of the Committee of the Bengal Economic Museum, originated in the efforts made by Mr. Thomas Wardle to collect information on the modes of dyeing the silks of India. This information was asked for so far back as 1875, and although the Indian Government were fully conscious of the importance of instituting an exhaustive inquiry upon the subject, it was not until 1880 that an instalment of the General Report was issued, and from this, for reasons which it is here unnecessary to enter into, the dyes of Bengal were omitted. Dr. M'Cann has doubtless done the best he could with the materials at his command, although there is a probability that the Report would have been fuller and more free from errors had it been possible to put together the information, which was mainly collected in 1875-77, at a time when the officers of the local governments and administrations through whom the information was obtained were still resident in their respective districts. As it is, the Report is avowedly incomplete, and in many points already out of date. The classification adopted is, in the main, the same as that already employed by Mr. Liotard in the Report on "Dyes of Indian Growth and Production" above referred to, but with the difference that Dr. M'Cann has preferred to give the methods of dyeing in connection with the accounts of the dye-stuffs themselves, instead of referring them to the fabrics which are dyed by them. The dyes are classed according to the colour they afford when used singly. One disadvantage of this arrangement is that some dye-stuffs which are used both alone and also in the preparation of compound colours are mentioned several times. Many of the dye-stuffs are called simply by their vernacular names, as they have not yet been botanically identified, and in many of the cases in which the scientific name of the specimen has been given there is nothing to show how it has been arrived at. In spite, however, of these imperfections, the Report adds considerably to our knowledge of the tinctorial resources of India, although it must be stated that owing to the delay in its compilation the original object of the inquiry has been in a great measure lost sight of. The primary object of the inquiry was, in fact, to obtain data upon which to base experiments with regard to the possibility of developing and improving methods of dyeing with native Indian dyes. Dr. M'Cann expresses the hope that this project may be revived. He is of opinion that among the vast number of Indian dyes there are many that might be developed into flourishing industries; but he is equally of opinion that this development will never take place through the native dyers themselves, who are content to follow the primitive methods handed down to them by their predecessors. Dr. M'Cann suggests that great results might follow if the Government would send out to India one or two trained chemists or scientific experts in dyeing to conduct experiments with the special object of developing native dyeing industries. The number of properly trained technical chemists already there is too small to hope for anything from them, nor is it likely that improvements will result from the private enterprise of European firms. As it seems nowadays the fashion to commend all such projects to the notice of the City Companies, it may not be out of place to draw the attention of the Worshipful Company of Dyers to the suggestion. T.

Lehrbuch der Vergleichenden Anatomie der Wirbelthiere. Von Prof. Dr. Robert Wiedersheim. Zweiter Theil. (Jena, 1883.)

WE have on a previous occasion (NATURE, vol. xxvi. p. 385) directed attention to the first part of Prof. Wiedersheim's text-book on the "Comparative Anatomy of the Vertebrata," which was published early in 1882. He has now, by the publication of the second part, completed the work, which forms a clearly printed and profusely illustrated volume of 906 pages, with 607 well executed woodcuts. The second part comprises a description of the alimentary, respiratory, circulatory, urinary, and generative organs of the Vertebrata, and the author tells us in his preface that the entire work represents the labour of six years. In his method of treating the anatomy of the viscera, described in this part, he has followed the same lines as in Part 1. The description of the modifications of each system of organs observed in the different classes of vertebrates is prefaced by a short chapter on the method of development of that system, and the subsequent description is then based on their developmental history. We can recommend the book as giving an excellent *résumé* of the subject written in a thoroughly scientific spirit.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Evolution of the Cetacea

IN the lecture by Prof. Flower "On Whales, Past and Present, and their Probable Origin," which appeared in your columns in June and July last, he contends for the evolution of these animals from the *Ungulata*, and points to the *Zeuglodons* of the older Tertiaries as predecessors of the *Balænoptera*, and as representing an intermediate stage in such evolution; and he insists on the absence of cetacean remains from any Mesozoic formations as strong evidence in support of this view.

I wish therefore to inquire whether Prof. Flower has considered the evidence afforded by *Palæocetus sedgwickii*, so named by Prof. H. G. Seeley from a set of anchylosed cervical vertebræ (one of which he figures), described by him in the *Geological Magazine* for February, 1865, p. 54.

Prof. Seeley states that the specimens were obtained from the boulder (chalky) clay near Ely, and that they were regarded both by the late Prof. Sedgwick and by himself as derived from either the Kimmeridge or the Oxford clay; and he quotes the opinion of Prof. Owen in the British Association reports, in his "British Fossil Mammals," and in his "Palæontology," that they belonged to an animal of the Dolphin group. Prof. Seeley himself regards this animal, for the reasons he assigns, as "not a cetacean of the Dolphin family, but a true whale, its affinity with the Balænoptera being, he says, singularly close"; and he concludes his description with a letter from a veteran student of the Cetacea, the late John Edward Gray, Keeper of the Zoological Department of the British Museum, who after pointing out the characters in which the fossils agreed with, and those in which they differed from, *Balæna*, asserted that in those particular respects the animal to which the remains belonged agreed with a genus of whales which he had just described under the name of *Macleayius*, from a specimen in the Australian Museum in Sydney. Perhaps Prof. Flower regards these vertebræ as not those of a cetacean at all; but if he agrees with the authorities just named on that point, the case seems to resolve itself into this, viz. either this whale lived in Mesozoic times, or its remains have come from some Tertiary formation. If the former, and particularly if its age is, as regarded by Prof. Sedgwick and Prof. Seeley, Jurassic, Prof. Flower's hypothesis of the evolution of the Cetacea from the Ungulates is hardly probable, when we consider the known facts as to the development of that group during the Tertiary period, even if we allow for whatever weight *Stereognathus* may afford of an approach to an Ungulate type in Jurassic times. If the latter, and these remains came originally from some older Tertiary formation, it follows that such a formation has, though no traces of it are now to be found, once existed in the area between Ely and the eastern watershed of the Pennine, because the whole of the material of the clay in which the remains were found is made up of the wreck of formations from that area alone. "Cosmic Dust"

THE report on Baron Nordenskjöld's expedition to Greenland this year, recently given in NATURE, undoubtedly contains important results as to the physical geography of that country. Its statements, of course, will require a more detailed explanation than this preliminary report can give; one statement especially, on account of its significance, induces me to call the reader's attention to a fact which it will be necessary to take into consideration in discussing the question.

The statement is contained in the following words at the end of the article:—"I hope when this (viz. the dust found on the inland ice) has been exhaustively analysed, to be able to furnish fresh proofs in support of the theory that this deposit is, at all events partly, of cosmic origin, and thereby contribute further materials for the theory of the formation of the earth."

The fact to which I have alluded is this: Next to the observations furnished by travelling over the inland ice, it appears to me that an examination of the fresh and pure fragments of it from the very interior of the country, which are pushed out in the shape of icebergs, must give the best key to the solution of the problem. We know that the mass of which these bergs are fragments is formed of snow accumulated during hundreds of years, and it has taken hundreds of years for the ice thus formed in the central regions to travel to the seashore. Consequently the dust which during the lapse of centuries has fallen upon the surface of the glacier must have been mixed up with the snow, and thereby spread over or embedded in the chief mass that constitutes the bergs.

As to my own observations, I have always found the chief mass that constitutes the large bergs to exhibit the appearance of perfectly pure ice, only permeated with thin air-bubbles, and the earthy matters of the bergs distinctly confined to isolated dykes, layers, conglomerates, or even to entire smaller bergs issuing from certain fjords. But I confess that my attention never was directed to a more minute investigation of the chief berg ice, and still less to the problem here mentioned. I do not remember to have seen anything mentioned by my friends Steenstrup, Helland, and Hammer that could throw sufficient light upon this question. I therefore here present it to your readers who are experienced in Arctic researches and may feel inclined to communicate their opinions upon it.

On the Incubation Period of Scientific Links

THE length of the dormant period during which a certain class of scientific discoveries has to remain unrecognised before they are made available is a subject that may form an interesting chapter in the history of science. I will cite one or two examples, in one of which I am personally interested, as illustrating my meaning, particularly as I think they will enable me to point out the cause of this strange anomaly at a time when so

years after they have been realised. As illustrating the fact that most important laws may remain for many years dormant, I have but to cite the law of Avogadro, which remained unnoticed for fifty years, until the investigations of Dumas proved it to be a most important aid in chemical research. The law of Dulong and Petit on the connection between the specific heat and the atomic weight of the elements had to pass through a dormant period of more than twenty years before it was resuscitated by the experiments of Regnault. More than forty years ago I announced a new law connecting the physiological reactions of inorganic substances with their isomorphous relations. This law, although founded on an extensive series of experiments, and since verified by the investigation of the action of the compounds of more than forty of the elements, has up to the present time remained entirely dormant, not having been noticed, as far as I am aware, by any writer on physiology. A French chemist, M. Rabuteau, has recently very cavalierly consigned it *aux baggages du passé*, apparently under the idea that it is a revival of the hypothesis that connected the action of poisons with the more or less acute angles of their crystals. Now, however, the important part played by these inorganic substances as physiological reagents is beginning to be recognised (see Ringer, *Journal of Physiology*, January and August, 1883; Brunton and Cash, *Proc. Roy. Soc.*, vol. xxxv.).

The question presents itself as to what there is peculiar in these laws which distinguishes them from those which find an immediate recognition by men of science. I think the distinction will be found in the fact that these hibernating laws generally form connecting links between two branches of science which had not, up to the time of the discovery of these laws, been of much mutual assistance. The law of Avogadro, for example, established a new link between chemistry and physics, and for its application the chemist had to be familiar with the manipulations required for the determination of the density of vapours and gases, a subject scarcely alluded to in treatises on chemistry at the beginning of the century. The law of Dulong and Petit forms another link between chemistry and physics, requiring for its verification methods which, at the time of its discovery, were almost exclusively in the hands of physicists. As for the law connecting the physiological action of a substance with its isomorphous relations, when it was first published the distance between chemistry and physiology was greater than that between physics and chemistry at the time of the discovery of Avogadro, and should the subject be already attracting the attention of physiologists, after a latent period of but forty-four years, this fact affords evidence that science is now advancing at a more rapid rate than formerly. The question is an interesting one as to the possibility of something being done to shorten the period during which these linking laws remain unrecognised. Offering, as they generally do, important aids for the advancement of science, it certainly is desirable that some means might be taken to prevent their being shelved amongst *les baggages du passé*, so that at some future period the whole subject has to be gone over *de novo*. In the case of physiological discoveries, it certainly would seem to be the duty of the Antivivisection Society to see that the many experiments which had been performed to verify them were made available, so that a great deal of vivisection might thus be avoided without the progress of science being retarded. San Francisco, November 13

Meteor

THIS afternoon, at 5.27 p.m., I observed here a meteor of great brilliancy, a note of which may be worth publishing. The moon, within three days of being full, was shining unclouded, and the western sky was still glowing with the fading tints of another gorgeous cloud-glow, when a bright light caused me to look up. It was due to a bright meteor a few degrees south of and below the moon. Its path was about 20° in length between south-east and south, inclined at an angle, roughly speaking, of 10° to the horizon, its mean altitude being probably 20°. Three minutes later, at 5.30 p.m., I heard a low, distant, rumbling sound, which was not improbably the report of its explosion.

Physical Society, November 10

UNDER the above heading in NATURE of Nov. 15, p. 71, I to be about 320 metres per second. This is manifestly a misprint for 330 metres, but I should like to state that as far as my experiments have gone the value for free air is not determined, although 330·6, Regnault's value, is probably very nearly what my method would make it. The Ophidian Genus "Simotes"

MY attention has just been drawn to a note by Mr. H. O. Forbes, published under the heading "The Genus Simotes of Snakes," in NATURE, vol. xxviii. p. 539, in which he states that, when describing a new species of *Simotes* discovered by him in Timor-Laut (*P.Z.S.* 1883) and which I observed was the first of the genus known to occur eastward of Java, I overlooked Krefft's *Simotes australis* from Port Curtis, described in *P.Z.S.* 1864. It is a well known fact, pointed out by Dr. Günther in 1865 (*Zool. Rec.* i.) and since admitted by Krefft himself ("The Snakes of Australia"), that *Simotes australis* is not a species of that innocuous genus, but belongs to a widely different family of *poisonous* snakes and to the genus *Brachyurophis*.

London, December 5 G. A. BOULENGER

THE REMARKABLE SUNSETS

WE have received the following further communications on this subject:—

HAVING been rather too persistently of late requested to explain both the why, and whence, and even the future influences, of the recent very red and brilliant sunsets, I gladly take the opportunity of addressing to NATURE the few remarks I have to make on the actual facts and their proximate causes.

In all truth the sunsets through the last week of November and first four or five days of December have been remarkably fine, and consecutively so numerous. But each one, in so far as I have observed, was but an intensification, and sometimes not much of that, of whatever goes to make up an ordinarily fine sunset, as customary to that season of the year and that direction of wind with its concomitant kind of clouds.

The season of the year not only causes the fiery show to last longer than at many other times but enables it to take place while pedestrians are still engaged in their constitutional afternoon walks in pleasant autumn temperature, and before they shut themselves up for the evening in their comfortable homes with artificial lights around them.

Some thirty years ago I used to spend every evening month after month, at the ordinary dinner hour of others, in the open air, watching for, and when seen making quick coloured drawings of, any exceptionally fine sunset; taking in this way three or four completely separate pictures on the same evening between the time of the sun vulgarly going down beneath the horizon, and at the last the stars coming out in the darkness after the last vestige of twilight or high illuminated cirrus-cloud had disappeared.

In this manner I came to know practically that the so-called after-glow, which has been alarming so many persons within the last few days, whenever the temporary disposition and arrangement of the clouds and vapour in the air allow it to appear, is always more richly coloured in reds of various kinds than any of the earlier glows and more luminous splendours; and that the number of modifications which any one sunset may go through, or the number of different pictures it may make up, according to changes in the clouds both above and below the horizon, is bewildering. But the grandest effects, the nearest approaches to the sublime, were always those when the general light in the air was either so faint, or so monochromatic, that the pigments in the colour box could not be distinguished one from another without the aid of artificial light.

On December 3 and 4 of this week, on setting myself to watch and note with my former apparatus, I found all these bizarre effects of colour and form in their old intensity and their old kaleidoscopic quickness of change. On the 3rd especially the reds were so powerful at certain times, and the air so clear between me and them, that the young crescent moon, though low down in the sky, shone by contrast to the scarlet cloudlets around it with a sort of supernatural lustre of blue silver; while the gas-lights under the same contrast, though in reality a gross beery brown in colour, appeared of a delicate sulphur, almost greenish, yellow. Those clouds, therefore, were so red in consequence of something that had happened to the sunlight illumining them which had not happened to that illumining the moon. What was it then? Simply that the lower atmosphere of the earth was so particularly clear of dust, haze, vapour, fogs, and positive obstructions of lower clouds that the sun, though at the time a long way below the horizon, was enabled to send its rays through an unusual length of atmospheric path without experiencing any other diminution than merely the specific elimination of those particular rays in its spectrum-quiver to which the atmosphere, in that particular condition, is antagonistic, leaving the field of glory to others alone.

Had the wind been *south*-west, the stoppage would have been chiefly amongst and of the red rays of light, where the black water-vapour lines are so numerous, chiefly below D, near C, and especially about the region of little "*a*," which then becomes of giant size. But the wind having been really *north*-west, the air was dry, water-vapour lines practically absent, and, as Col. Donnelly most correctly remarked in this week's NATURE (p. 132), the dry air band above D in the citron, and usually called the low sun band in meteorological spectroscopy, was at an immense maximum. Red light was therefore practically unimpeded, green and blue much interfered with, and more and more with every successive instant of further descent of the sun below the horizon. So thus it was that the spectroscope told at any instant through all the varied displays that that coloured light so much admired was simply sunlight that had passed through an extra length of extra-dry air, and was being reflected at the last from thin clouds at an extra height in the atmosphere, where water-vapour is always at a minimum.

But the sunset of December 5 was very different. In the course of the evening there were two or three distinct attempts, as it were, for the clouds to assume red hues, but they lasted for only a few seconds each; and though some aspects of the scene were very fine pictorially, it had to be classed as a "yellow sunset." Next day showed the cause of that in the wind below, as well as above, turning round to east of north. December 6 and 7 had poorer and poorer sunsets of both a yellow and sickly type, and December 8 with a south-west wind has brought in rain.

Thus seems to have ended for the time this fine series of Nature's evening pyrotechnic displays in the west (a similar set having also been witnessed during the mornings in the east); but demands are still made for an explanation of why, and to what end? If we should reply that, given a clear air, not too many clouds, and these high up in the atmosphere and with surfaces well constituted for reflection, the sunsets will always be fine; and that they will be varied exceedingly in their beauty even from moment to moment, according to the exquisite manner in which clouds and cloudlets of cirrus streamers form and dissolve and form again in all varieties of shape and size and density, according to mere temperature changes and other ordinary meteorological conditions of the air; that is not enough to satisfy the present temper of the public, who seem screwed up to a pitch of nervous alarm that what they have been seeing, though to them it has been like "music which gives delight and hurts not," may yet have something to do with the green and blue suns seen in India last September, and they with the great volcanic explosions in Java last August, so destructive of human life!

The said green and blue suns were, however, quite a different phenomenon to our red sunsets. For, instead of appearing extra bright and contrasted in colour with clouds near them, like the crescent moon of December 3 just mentioned, they were abnormally faint, and uniformly tinged with both clouds and fog, and moon and stars at night. Moreover, the spectroscope, in the able hands of Prof. Michie Smith of Madras College, showed that the intervening medium, through which the sun's light was struggling towards these Indian observers, was extra damp instead of extra dry. And in the west of India since then, as we have just heard from private sources, no less than 140 inches of rain have fallen, and the country was in a temporarily impassable condition from sloppy softness of soil.

Prof. Michie Smith has indeed entertained the idea that the particular state of the watery vapour which cut off so largely the red, but passed on the green light of the sun's spectrum in a weakened condition, may have been owing in some degree to particles of pumice dust from the Javan volcanoes. And such dust, once up in the air, may circulate around the earth, after the manner which Commander Maury, U.S.N., was so earnest in teaching with respect to the trade winds and their spiral paths through either hemisphere.

But how long such dust would remain suspended, how high it would rise, and when and where it would fall, are questions that can hardly be answered positively and with exactitude *a priori*. It did not fall, so far as we have heard, in India, where, if present at all, it must have been comparatively low and dense. And it was not falling here during the recent red sunsets, for the lower air was particularly clear, while the supposed criminating redness was too manifestly due to the extraordinary height, as well set forth by Prof. Helmholtz, of the uppermost cloud stratum, a thin kind of cirrus haze, according to my observation, combined with the discriminating action of the atmosphere on the compound coloured solar light.

Why that cloudhaze was so high, and whether dust, and if so what dust, had any part in its constitution, are questions which may worthily be discussed, but no very certain answers expected for years to come. But having been myself much struck during a rather long residence on the Peak of Teneriffe in 1856, with the general and apparently normal existence of dust strata in the atmosphere, higher or lower, but often far above the level of ordinary water-vapour clouds,—and as the meteoric researches of Prof. Newton, corroborated by Prof. C. A. Young, in America, show that not less than 100 tons of meteoric stones (of which the earth encounters nearly 3,000,000,000 in the course of a year) must be dissipated in our upper atmosphere on the average *every day*, as impalpable dust,—it seems more probable that Prof. Helmholtz's very high clouds, if they were assisted in putting in an appearance as clouds by dust of any kind, must have derived it from such disintegrated and sublimed meteor-masses coming down day by day in the regular way of nature from above, or outside, rather than from a supposed continued ascent of one particular charge of volcanic dust from Java, full three months after the cessation of all violent disturbance there.

In fact while it is to be earnestly hoped, as an outcome of the late remarkable sunsets, and the great numbers of the public by whom they have been witnessed,—that our painters will no longer be content to give us so generally mere afternoon pictures slightly yellow ochred and "light red"-ed near the horizon before the sun goes down, as sunsets,—but will more frequently paint the deep red afterglows at their richest;—it is equally desirable that our scientists should gauge the ordinary constitution of the atmosphere at much greater heights than those to which observatories are usually confined.

C. Piazzi Smyth,
Astronomer Royal for Scotland
15, Royal Terrace, Edinburgh, ♄ December 8

The following summary of atmospheric effects seen before sunrise and after sunset between November 25 and December 11 may be useful for comparison with phenomena observed in other parts of the world:—

November 24.—After sunset, yellowish-green striæ in west.

November 25.—Sunset in amorphous apparent cirro-stratus or cirrus haze. Green light above it, and bright greenish-white arc growing from about ten minutes after sunset; above the greenish-white, pale red. Lasted about forty-five minutes after sunset. The sky shone with a strange light somewhat as on November 9, but much feebler, and there was no sharply marked aggregation of cloudy reflecting material as then.

November 26.—Fine clear sunset, followed by phenomena like yesterday, but much stronger, and lasting nearly an hour bright red. No high clouds seen as light receded from the sky. A few rounded morsels of cumulus fringed with green against the red sky. Very strange effect, the greenish-white light in the west, and pink above.

November 27.—Sunset effect like yesterday, beginning to glow about fifteen minutes after sunset, and growing slowly in apparent brightness. Lasted till about 5.20. Slight, thin cirrus.

November 28.—Slight cirrus. Clear sunset. About twenty-five minutes after sunset green and pink glow began and grew bright and finely-coloured till about 4.40. Then slowly receded till about 5.10, when it disappeared, and was succeeded by a faint brass-coloured after-glow reaching high above the horizon. Time of sunset, 3.55.

November 29.—Extraordinary red glow, said to be seen in London from 5.30 to 7.30 a.m. Cloudy evening. At 4.55 a dull faint red glow observed through a small break in the clouds. Time of sunrise, 7.43.

November 30.—At 6.5 a.m. (and probably a few minutes before) a fine deep red glow in the east and overhead, where small quantities of cirro-cumuli seemed to be touched by the reflected light. At 6.15 a faint, deep red glow had spread from north-north-east to south-east, and up to about 40° above the horizon in the north-east, covering a vast portion of the sky. Then gradually became whiter and less striking. The blood-red band in darkness at 6.10 most remarkable. The glow continued (slowly changing in colour and growing in extent), and was evidently independent of ordinary clouds. The bright stars appeared through it. At 6.24 a faint red light extended to the zenith. At 6.40 the red had gone, and was replaced by a primrose colour, the flocks of cirro-cumuli, however, still remaining tipped with bright red, and retaining that colour till sunrise (7.44). There was no cirrus visible, and the reflecting haze was invisible both by night and in full daylight. The cirro-cumulus was moving moderately fast from west-north-west. The red bank in the east was not crowned with shafts of rays or prominences as in the sunsets of November 26, 27, and 28, but the intensity of the light diminished continuously upwards from near the horizon. The afternoon being cloudy, the only thing observed was a dull greenish light about half an hour after sunset.

December 1.—Sunrise cloudy. Sunset (3.53) in cloudy sky, except near horizon. At 4.25 slight tinge appeared on fringes of clouds overhead. Then densely clouded. At 5 the sky had cleared largely, and a fine amber light could now be seen from near the west horizon to about 40°. This gradually sank, following the sun, and grew less bright, finally disappearing about 5.35. Sky clear and starlight, except low strips of cloud near the horizon, Centre of maximum brightness followed the sun, as usual. The light as it sank near the horizon was quite without definite outline or the ray shafts which appeared on previous evenings with a clear sky.

December 2.—Sunrise cloudy. Cloudy at sunset, but clouds partially clearing off. Thin fog on low ground. Bank of clouds in west. Sunset 3.53. At 4.20 faint amber glow above cloud-bank, growing in strength as darkness came on. At 4 10 the sky towards the zenith from the west was crossed by spokes of light as from the thinnest possible cirrus streaks, diverging from the sun's place as centre, and some of these nearly overhead became somewhat bent after a few minutes. The thin clouds scattered about evidently caught some light from a hidden source. At 5 p.m. the light was pale yellow, and had moved northwards. At 5.10 disappeared behind cloud-bank.

December 3.—Cloudy.

December 4.—Very fine and clear morning at 5 a.m. At 6.5 a.m. the first blush of red appeared over the plantation (about 400 yards off) due east, and by 6.10 was quite bright, like the reflection of a fire. It grew quickly upwards, and by 6.15 must have been 15° above the horizon. It appeared uniform and amorphous. By 6.30 the red had changed slowly to saffron, and being seen less in perspective, the colour seemed less concentrated. The reflecting material, or a part of it, was now seen to consist of ill-defined streaks and patches of very thin misty cloud of some sort, in which after long watching from suitable positions no motion could be detected, though distinct streaks nearly overhead were chosen. At 6.45 some of hese streaks were illuminated nearly overhead southwards of a pale straw-colour and bluish white, and their outlines were distinct. Most of the streaks stretched about west-south-west to east-north-east, and towards the north-east the appearance was like a fretwork of the ightest wavy mist. From 6.30 to 6.50 the coloured arc was of a sickly yellowish green, with a pale pink towards the enith and a rather ghastly steel-white glare below. At 6.53 a second glow much brighter than the first appeared n the east-south-east by south, of a deep red colour, quickly turning to orange. This glow was in a bank or arc much better defined than the first. At 7.10 it had urned quite yellow and had grown up many degrees. At 7.16 the last star disappeared in the bright light now cast on all objects towards the west, the clear sky as the light touched the thin high mist appearing progressively veiled with opaque cloud. Just before he advent of the second glow the thin cloudy streaks had nearly vanished into pure blue sky. At 7.12 the upper part of arc No. 2 was pinkish yellow, with a greenish-white centre below. At 7.20 the part below the arc and along the horizon south and north for some dis-ance was a peculiar steely-bluish white, the lower part of he arc yellow, and the upper pink (at an altitude of about 0°). These effects slowly diminished, but the steely hue emained till sunrise. At 7.23 the sky overhead and owards the west was faint pink, with large billowy treaks and patches, without fibrous structure. In full daylight only faint traces of this cloudiness could be een, but the rising sun, like the first and second glow, made it manifest. The sun rose (7.50) of a ed colour, but after about half an hour was pale bluish white, and surrounded by a silver-white glare. As the sun was setting (3.53), the high haze again appeared by reflection to cloud over the sky. Nothing otherwise very remarkable appeared till about 4.12, when t was evident the phenomenon would recur, the central spot above the sun's place being bright steel or lead colour, and the parts round it a metallic pink. This has been the usual preliminary. The sky in the east was rosy. The rose colour quickly passed over towards the west, and about 4.20 the whole sky between the west horizon and the zenith was flushed with red. At 4 25 or thereabouts the crescent moon appeared blue in this pink haze, but in a few minutes was left behind by it, and looked much as usual. The small, greasy scud from north was lighted up pink in the east against a deep blue and greenish sky. As the glow sank westwards, the sky above seemed perfectly clear. At 4.35 the light was very bright, and at 4.45 was lost to view behind low clouds. As soon as it approached the horizon, the sky again became streaked with the reflecting haze, which assumed a straw-coloured tint. This pale light sank westwards and disappeared soon after 5. The moon and stars gave no indication of a haze canopy.

December 5.—Exactly at 6.5 a.m. the first faint red blush grew up quickly from east-south-east, and in seven or eight minutes had increased largely in brightness and extent. The night was very fine and clear, and the soft, crimson glow hanging above the horizon in the darkness produced an interesting effect. It grew rapidly up towards the zenith, and at 6.18 formed an arc of which the highest point was about 40° above the horizon. After this it quickly changed to orange and yellow, and the colours went off. The arc was more southerly than yesterday, and the peculiar light reached from south-south-west to east-north-east. At 6.55 the second glow began, and rising up quickly, produced a fine red arc, less bright than yesterday's. At 7.6 the arc was olive-green below, yellow in the central, and pink in the outer parts, and hardly any cloudy structure could be discerned. What there was, however, resembled the film of yesterday. The upper edge of the glow was pretty well marked as it advanced, and at 7.12 it crossed the zenith and passed north-westwards, covering a bright star with a thin pink veil. This star remained visible till 7.21. After this the sky was pale yellow, and soon little remarkable remained, except the greenish light in the south-east. Sunrise 7.51; red sun, turning silvery white later. Sunset 3.50 in hazy striæ. Clear sky, except slight cirrus. At 4.15 yellow glow, which went through changes as usual. The light was pink overhead, and the margin passed the zenith about 4.26. At this moment it may be supposed the sun was sinking below the horizon at the altitude of the reflecting material At 4.30 the moon looked blue in a pink haze. Spokes of rays from the glowing bank at 4.45. Some threatening cirro-stratus passed over at 4.45. Horizon misty. Crescent moon greenish all the evening.

December 6.—Sky very clear 6 a.m. First rose colour 6.10. Much fainter than previously. Second glow 6.58. Detached scud from 6.45 tinged with red on blue sky. Sunset clear, except small detached scud. The light in the west was fine, and went through changes, but was red from 4.20 to 5.5 p.m. The glow seemed to be reflected from some strips of apparent cirrus about 15° above the horizon. During all this time the small clouds scattered in all parts of the sky were of a pink colour against a greenish and later a deep blue sky.

December 7.—Cirrus streaks in west turned *black* against pinkish yellow glow, 4.24. Sun looked quite green through telescopic dark glass fifteen minutes before sunset.

December 11.—Fine sunrise and sunset phenomena, the secondary glow after sunset lasting till 5.33. Steel and pink halo from 12.45 p.m. Sky clear blue, at first glance, by night and full daylight, but, examined with light from below at a certain angle, seen to be quite covered with hazy billows or striæ, stretching away from north-north-east to south-south-west, very much higher than the cirrus present, and after long watching showing extremely slow tranverse motion from about west-north-west. Unlike cirrus fibres, whichever way looked at they appeared nearly parallel, without radiant point, even the lines just above the horizon showing their true direction almost exactly. Sun green through dark glass.

It seems pretty clear that the secondary light which has always succeeded the primary after sunset, and preceded it before sunrise, is due to reflection from the first when this is at a proper angle near the horizon. The interval between the same stages of the secondary and the primary before sunrise, when conditions are most favourable for accurate observation, is about fifty-on minutes, and the interval between the more conspicuous primary and the actual sunrise about fifty-six minutes. The first red colour of the primary glow may be caused by the incidence of the sun's first rays upon the material. It seems that the reflecting material directly overhead receives the sun's rays about thirty-nine minutes earlier at sunrise, and loses them as much later at sunset, than the surface of the earth. I have not found the colour effects in many cases to be subjective. A green cloud remains green when cut off from surrounding light. May not atmospheric sifting produce the surviving colour?

F. A. R. RUSSELL

THE Hon. A. P. Hensman, Attorney-General of West Australia, writes to me as follows, under date of Perth, West Australia, October 27:—"The captain of a ship lately engaged in a survey of our north-western coast at the time of the eruption in the Straits of Sunda told me that the deck was covered to a depth of an inch or more with a fine dust. We are having, and have had for many weeks, very remarkable sunsets. After the sun has set, a glow commences somewhat high up above the horizon, a brilliant rose-colour; this continues for nearly an hour, gradually descending to the horizon, and becoming deeper in colour. It has never been seen here before, and has given rise to much speculation amongst learned and unlearned, both here and in the other colonies; some suggesting that it is caused by the presence of volcanic dust in the atmosphere." This extract may be of interest to your readers, as showing that all over Australia similar phenomena have been observed to those discussed in your pages.

As I am engaged in making a comparative study of the dust which fell at different points during the Krakatoa eruption, I shall feel greatly obliged to any of your readers who can supply me with samples of such dust, accompanied by a note of the time and place of the fall.

JOHN W. JUDD

Science Schools, South Kensington, S.W., Dec. 8

THE uncommon phenomenon witnessed in various parts of India, Ceylon, and the Cape of Good Hope, has made its appearance here. The sun, immediately it sets behind the ridge of Possilipo, throws upwards a group of red rays somewhat irregular in arrangement; the sky begins then to assume a greenish tint. These rays soon disappear, and then the whole horizon for 180° is lit up by a bright orange-red light, which gradually deepens in tint. The height of this light does not usually extend above 25° or 30° at its centre, and gradually descends to the level of the horizon at its two extremities. So far as I can make out, the centre or most brilliant point of this is quite 20° more to the south than the setting sun. All the south-west sides of the houses are suddenly lit up by this peculiar lurid glare, which is best compared to the colour of incandescent iron, and reflected from the surface of the sea makes the gulf look like a veritable lake of molten lava. The effects last at the maximum only an hour after the setting of the sun. On Sunday last the moon, shining through this red glare, had a bluish tinge of the arc electric light colour. The same phenomena precede sunrise. These effects are quite independent of clouds, which, when present, have a deep lead colour, and their edges are not illuminated. The weather is cold, the wind variable, chiefly north or north-east. The magnetic instruments at the observatory show no disturbances, which excludes the possibility of an aurora, as also its presence *only* when the sun is just below the horizon. I send these notes, hoping they may be an addition to the other observations already published in NATURE, to aid in an explanation of this remarkable and widespread phenomenon.

H. J. JOHNSTON-LAVIS

Naples, December 6

SIR ADAM BITTLESTON presents his compliments to the Editor of NATURE and ventures to send him an extract from a letter written by Sir Adam's son at Umballa (lat. 30° N.) on October 30. There seems a long interval of time between the appearances at Ongole (September 10) and those noticed at Umballa.

87, Linden Gardens, Bayswater Road, W.,
December 10

Extract from a Letter from Lieut. G. H. Bittleston, R.H.A., dated Umballa, October 30, 1883

"There has been *for some time* a remarkable appearance in the sky every night. The sun goes down as usual and it gets nearly dark, and then a bright red and yellow and green and purple blaze comes in the sky and makes it lighter again. It is most uncanny, and makes one feel as if something out of the common was going to happen."

THE inclosed from the *Hawaiian Gazette*, October 3 may interest students of meteorology.

F. J. S.

"*Maui.*—With regard to the extraordinary sunsets, a correspondent in Wailuku writes:—'I do not know what kind of sunsets you are having in Honolulu, but here for some time past they have been most extraordinary. Fiery red, spreading a lurid glare over all the heavens, and producing a most weird effect.'

"*Kauai.*—The peculiar sunsets have been noticed and commented on by the Kauai people. No one has ventured on a theory here."

THE line of green suns is carried further west to Panama, where, according to the *Star and Herald*, the phenomenon was observed on September 2 and 3, and it is suggested to be in connection with Krakatoa.

HYDE CLARKE

32, St. George's Square, S.W., December 8

I SEND you a bottle of volcanic dust which Capt. Robert Williams of the bark *Arabella* obtained under the following circumstances. He says:—"On Tuesday morning, August 28, 1883, it commenced to rain something like sand (some of which I collected from off the decks), which kept on all this day and the next day. Lat. at noon of the 28th, 5° 37′ S., long. 88° 58′ E., wind light from the west-south-west, and calm at times. Java Head bearing east half south, distant about 970 miles." Can this shower be connected with the Java eruption?

Falmouth, December 6 HOWARD FOX

AS accuracy of observation is before all things desirable in the elucidation of natural phenomena, I hope you will allow me to point out an error into which some of our physicists appear to have fallen in connection with the green moon which was visible in the evenings of Tuesday and Wednesday of last week. Mr. Norman Lockyer, in his admirable article in the *Times* of Saturday last, refers to "the subjective colouring which cast a green glamour over moon and cloud if one did not take the precaution of preventing the eye being flooded by the rosy pink visible in the zenith long after sunset;" and a writer on recent solar phenomena in the *Daily News* says, "This latest phenomenon has caused a greater amount of astonishment than the earlier ones, but, unlike them, admits of very easy explanation, for a moment's reflection will show that on a pink background a white moon could scarcely appear anything but green," thus, like Mr. Lockyer, attributing the phenomenon to the presence of a complementary colour. What I wish to point out is that there is no foundation for this theory. I observed the effect most carefully on both evenings. On the second evening especially I looked with the object of ascertaining whether the effect was due to a complementary tint, and am thoroughly convinced it was not. At four o'clock, or a little after, the moon was distinctly green on a blue-gray sky-ground, with very thin gray cloud-drift floating over it. At the same time the whole of the western sky was lit up with a very pale whitish-yellow, to which neither blue nor green would be complementary. There was not a vestige of crimson or rose colour at that time in any part of the sky. Later, when the crimson supervened, the green tint of the moon was only very slightly intensified, so slightly indeed as to leave me still in doubt whether there was any change at all. It stands to reason, moreover, that if the result were due to the presence of crimson in the sky we should frequently see a green moon. Some other cause must therefore be sought in explanation of this new phenomenon. If we may accept Mr. Lockyer's conclusions with regard to volcanic action—and he certainly establishes a very strong case—the cause is not far to seek. It would be especially interesting to ascertain over how wide an area the effect was visible. Some records from observers at a distance would be very valuable.

Ealing, December 10 SYDNEY HODGES

P.S.—In quoting my letter to the *Standard* last week you gave a wrong name—Hooper instead of Hodges.

THERE is one point in connection with this subject to which much attention has not been given, namely, the increase of light, especially in the morning. Having slept out of town lately, I have been able to watch the sunrises, and to be exact I will describe in few words what occurred on Wednesday last, December 5. The eastern horizon is bounded by a hill some 50 feet high as seen from my house. At 6 a.m. I saw, rising in a semicircular form above the horizon, and tolerably defined in outline, a beautiful red coloration of the sky. The colour spread along the horizon in a westerly direction, and at 6.30 the entire vault of heaven was suffused with this red colour. When it was first noticed, namely at 6 o'clock, the light was sufficient to illumine the garden, as in the early morning in summer. At 6.15 the light was sufficiently strong to enable me to read the figures on my pocket-watch at the head of my bed, namely eighteen feet away from the window. The sun rose above the horizon at 8h. 5m., and at 10° farther west than the first burst of colour which I noticed. As the sun rose, the red colour disappeared, and it was entirely lost before the sun was fully in view. I am told by friends who were in Düsseldorf on November 30 that at 6 o'clock on that morning their rooms were lighted up so that everything was plainly visible. They at first supposed that the light was produced by a large fire opposite; but they soon discovered that it arose from this red light which you have now so well explained.

December 10 B. E. BRODHURST

NOT having noticed any letter in NATURE stating that the remarkable red glow seen in so many places after sunset was also observed in Ireland, perhaps you will permit me to mention that during the past fortnight, and especially since the 24th ult., it has attracted much attention here. This day week my steward insisted that the heather was on fire on the hills and that we were only watching its reflection. Since then the phenomenon has been even more remarkable, and the farm labourers have been enabled to remain at work in the fields ten to fifteen minutes later than usual. A bank of cloud generally separates the red glow from the horizon. Before sunrise the sky has sometimes a strange reddish look, and at 4 a.m. on the 29th ult. the brilliant roseate hue (referred to in the *Times* as having been seen in London at 5 a.m.) was witnessed here. RICHARD M. BARRINGTON

Fassaroe, Bray, Co. Wicklow, December 2

ACCORDING to a letter from my brother, dated Yokohama, September 22 last, the sun was completely obscured there two days after the earthquake took place in the Straits of Sunda. He writes:—"What a terrible earthquake that must have been in the Straits of Sunda. Incredible as it may appear, two days afterwards the sun here was completely obscured, and, on its reappearance, was quite *blood red*, while every now and then jets that looked like smoke passed across its disk. This lasted for two days," and he adds that "it is conjectured that this is caused by the volcanic smoke and ashes having been driven up here by the south-west monsoon."

32, Fenchurch Street, E.C., Dec. 8 W. HAMILTON

A FEW days since I was mentioning to my family that I remembered how splendid the colouring of the sky was at Malta after sunset in the year that "Graham's Island" appeared. In this morning's *Times* that island is alluded to, and I think you may be interested in the perusal of the accompanying pamphlet (printed for private circulation only). My father (Capt. Sir le Fleming Senhouse, K.C.H.), you will see, landed on the island, and named it after the then First Lord of the Admiralty. The great beauty of the sunsets we have been having have forcibly reminded me of the colouring I saw so many years since at Malta.

Hillside, Guildford, Dec. 8 ELIZABETH M. PITMAN

A correspondent sends the following:—

IT may interest your readers to know that in reference to the splendid sunsets we have seen in England lately I received in a letter from Lieut. C. K. Hope, R.N. (*en route* by inshore passage to the Cape of Good Hope) the following account of an extraordinary phenomenon witnessed by him on October 26 soon after crossing the equator:—"H.M.S. *Orontes*, October 26.—Last evening shortly after sunset the sky bearing from us between north-west and south-west suddenly burst into a red glowing light; the highest point attained an altitude of probably 35° or 40°, and from there tapered gradually away on both sides to the horizon. It showed brightest about 7.15, it being nearly dark at the time, and lasted till 7.30, gradually dying away till about 8 o'clock, when very little of it was left. I could have understood the phenomenon if we had been 40° further north or 20° further south, but on the edge of the tropics such a thing is very strange."

December 5

THE JAVA ERUPTIONS AND EARTHQUAKE WAVES

THE following communications have been sent us for publication by the Hydrographer of the Admiralty:—

Extract from a letter of Commander the Hon. Foley C. P. Vereker, of H.M.S. *Magpie*, dated Labuan Island, October 1, 1883:—

". . . The noise of the detonations caused by Mount Krakatoa, resembling distant, heavy cannonading, was distinctly heard by us and the inhabitants of this coast as far as Bangney Island on August 27. The weather at that time was also much unsettled, with thick hazy weather, and peculiar clouds to the southward, and the sun while at a low altitude assumed a greenish hue for several days. . . ."

Extract from a letter of Staff-Commander Coghlan, R.N.:—

"*Western Australia, Perth, September* 14, 1883.—This coast has been visited by waves and volcanic disturbances (sounds as of the firing of guns inland, &c.), apparently associated with the Sunda Strait outbreak.

"News is anxiously looked for from our north-west coast, as a wave 15 feet high, coming at high water, would lay Cossack, the mouth of De Grey River, Carnarvon (north of Gascoyne), and other places under water. In Champion Bay a wave rose 8 feet above the usual high-water mark. At Fremantle, King George's Sound, and along the south coast, a wave of less height was experienced

"The *Meda*, on our passage down from Ashburton River (when distant from 50 to 100 miles off the west coast of Australia, and about 1000 miles south-south-east of Sunda Strait), was visited by a shower of volcanic dust (in appearance like prepared "fuller's earth"), which fell some time between sunset of August 30 and sunrise of August 31, the wind being on-shore at the time.

"If the dust were associated with the disturbances in Sunda Strait of August 27 and 28, it must have travelled 1050 miles in three days."

BICENTENARY OF BACTERIA

[We have received the two following communications on this subject:—Ed.]

At the present time, when so many anniversaries of great men and great events are celebrated, it seems opportune to remember that exactly two centuries have passed since a discovery of the greatest consequence was made in the Netherlands. In a letter dated September 14, 1683, from Delft, to Francis Aston, F.R.S., of London, Antony van Leeuwenhoek gives notice to the Royal Society that with the aid of his microscope he has discovered in the white substance adhering to his teeth very little animals moving in a very lively fashion ("animalcula admodum exigua jucundissimo modo sese moventia." "Arcana naturæ detecta," Delft, 1695: "Experimenta et Contemplationes," p. 42). *They were the first Bacteria the human eye ever saw.* Among them Leeuwenhoek distinguishes several species, the descriptions and drawings of which are so correct that we may easily recognise them. The rods, with rapid movement penetrating the water like fishes, are *Bacilli;* the smaller ones rotating on the top are *Bacterium;* one undulating species is *Vibrio rugula;* the parallel threads of unequal length [illegible] motionless, they belong to the moving Bacilli. Leeuwenhoek wonders how, notwithstanding the scrupulous care with which he cleans his teeth, there could live more animalculæ in his mouth than men in all the provinces of the States-General. Some years later, not perceiving again the movements of the Bacteria between his teeth, he supposes he had killed them by taking hot coffee at breakfast; but very soon he discovers anew the old species, and the new drawings of Bacillus and Leptothrix which he sends to the Royal Society in the middle of September, 1692 (*l.c.*, p. 336) are still more accurate than those of 1683. They have not been surpassed till within the last ten years. It deserves our highest admiration that the first discoverer of the invisible world could already reach a limit which has never been overstepped, though the members of the Royal Society, when considering two hundred years ago the curious communications of the philosopher of Delft, may have scarcely foreseen that his astonishing discovery had opened to science a new path which only in our own days has led to the most important revelations about fermentation and disease. Ferdinand Cohn

Breslau, November 27

It cannot be a matter of indifference to English men of science, and especially to the Fellows of the Royal Society, that the bicentenary of the discovery of those immensely important agents of putrefaction, fermentation, and disease, the Bacteria, is at hand.

It was to the Royal Society of London that Antony van Leeuwenhoek communicated his discovery, and we may be sure that neither he nor the Royal Society of that day anticipated the extraordinary interest which would attach itself in two centuries' time to the organisms discovered by the patient and accurate student of minute life.

Leeuwenhoek's "discovery" is a remarkable example of that unexpected giving of rich gifts to future generations of men which marks the progress of scientific research in all its branches. It is for the Royal Society to devise some means of celebrating this bicentenary in such a fashion as to use the great interest and even fascination which Bacteria have at this moment for the English public, so as to excite sympathy with pure and unremunerative scientific research. Antony van Leeuwenhoek is the type of the single-minded student of living structures. The investigation of the properties and life-history of Bacteria, although commenced by him two hundred years ago, is still in its infancy. Schwann, Pasteur, Lister, Cohn, Nägeli, and Koch have brought us within the last fifty years far beyond Leeuwenhoek's first discovery, but a hundred such men are needed to carry on the work of discovery. Who will employ them? Are we to wait two centuries more for knowledge about Bacteria which lies, as it were, ready to our hands, waiting to be picked up? knowledge which will probably save many thousands of lives annually—if we may judge by the results already attained by the discovery of the relation of Bacteria to the suppuration of wounds and to the production of diseases.

The Royal Society could not better celebrate the bicentenary of its Dutch correspondent's discovery than by taking steps to urge on the English Government the expenditure of ample funds upon a new and vigorous prosecution of the study of the relations of Bacteria to disease, in fact upon the foundation of a national laboratory of hygiene. L.

THE UPPER CURRENTS OF THE ATMOSPHERE

All winds are caused directly by differences of atmospheric pressure, just in the same way that the flow of rivers is caused by differences of level; the motion of the air and that of the water being equally referable to gravitation. The wind blows from a region of higher towards a region of lower pressure, or from where there is a surplus to where there is a deficiency of air. Every isobaric map, showing the distribution of the mass of the atmosphere over any portion of the earth's surface, indicates a disturbance more or less considerable of atmospheric equilibrium, together with general movements of the atmosphere from regions of high pressure towards and in upon low-pressure areas. All observation shows, further, that the prevailing winds of any region at any season are merely the expression of the atmospheric movements which result from the disturbance of the equilibrium of the atmosphere shown by the isobaric maps as prevailing at that season and over that region. All observation shows, in a manner equally clear and uniform, that the wind does not blow directly from the region of high towards that of low pressure, but that, in the northern hemisphere, the region of lowest pressure is to the left hand of the direction towards which the wind blows, and in the southern hemisphere to the right of it. This direction of the wind in respect of the distribution of the pressure is known as Buys Ballot's Law of the Winds, according to which the angle formed by a line drawn to the centre of lowest pressure from the observer's position, and a line drawn in the direction of the wind is not a right angle, but an angle of from 60° to 80°. This law absolutely holds good for all heights up to the greatest height in the atmosphere at which there are a sufficient number of stations for drawing the isobarics for that height; and the proof from the whole field of observation is so uniform and complete that it cannot admit of any reasonable doubt that the same law holds good for all heights of the atmosphere.

In low latitudes, at great elevations, atmospheric pressure is greater than it is in higher latitudes at the same height, for the obvious reason that owing to the lower temperature of higher latitudes the air is more condensed in the lower strata, thus leaving a less pressure of air at great heights. It follows that the steepest barometric gradients for the upper currents of the atmosphere will be formed during the coldest months of the year. At Bogota, 8727 feet in height, where the temperature is nearly uniform throughout the year, the mean pressure for January and July are 22·048 and 22·058 inches. On the other hand, at Mount Washington, 6285 feet high, where the January and July mean temperatures are 6°·4 and 48°·2, the mean pressures for the same months are 23·392 and 23·875 inches. Similarly at Pike's Peak, 14,151 feet high, the mean temperatures are 3°·1, and 39°·7, and the mean pressures 17·493 and 18·069 inches; and since the sea-level pressures in the region of Pike's Peak are nearly 0·500 inch higher in January than in July, it follows that the lowering of the pressure on the top of Pike's Peak due to the lower temperature of January is upwards of 1·000 inch. From the greatly steeper barometric gradients thus formed for upper currents during the cold months of the year from equatorial to polar regions, these currents attain their maximum strength in winter and converge upon those regions of the earth where the mean temperature is lowest.

As is now well known, atmospheric pressure in summer is lowest in the central regions of the continents of Asia, Africa, and America; and highest in the Atlantic between Africa and the United States, and in the Pacific between the United States and Japan, the absolutely lowest being in Asia, where temperature is relatively highest with respect to the regions immediately surrounding, and absolutely lowest in the Atlantic, which is most completely surrounded with highly-heated continental lands. Again, in winter the lowest atmospheric pressures are found in the north of the Atlantic and Pacific Oceans, where temperature is relatively highest, latitude for latitude; and the highest pressures towards the centres of the continents, some distance to southward of the regions where at this season abnormally low temperatures are lowest.

The causes which bring about an unequal distribution of the mass of the atmosphere are the temperature and the moisture considered with respect to the geographical distribution of land and water. Owing to the different relations of land and water to temperature, the summer temperature of continents much exceeds that of the ocean in the same latitudes; and hence results the abnormally high temperature of the interior of Asia, Africa, America, and Australia during their respective summers, in consequence of which the air becoming specifically lighter ascends in enormous columns thousands of miles in diameter. Winds from the ocean set in all round to take the place of the air thus removed, raising the rainfall to the annual maximum, and still further diminishing the atmospheric pressure. On the other hand, since in winter the temperature of the continents and their atmosphere falls abnormally low, the air becomes more condensed in the lower strata, and pressure is thereby diminished in the upper regions over the continents. Upper currents set in all round upon the continents, and thus the sea-level pressures become still further increased. Hence the absolutely highest mean pressure occurring anywhere on the globe at any season, about 30·500 inches, occurs in Africa in the depth of winter.

Now observation conclusively proves that from the region of high pressure in the interior of Asia in winter, from the region of high pressure in the Atlantic in summer, and from all other regions of high pressure, the winds blow outwards in all directions; and that towards the region of low pressure in Asia in summer, towards the region of low pressure in the north of the Atlantic in winter, and towards all other regions of low pressure, whenever and wherever they occur, the winds blow in an in-moving spiral course.

Since enormous masses of air are in this way poured into the region where pressure is low without increasing that pressure, and enormous masses of air flow out of the region where pressure is high without diminishing that pressure, it is simply a necessary inference to conclude that the masses of air poured all round into the region of low normal pressure do not accumulate over that region, but must somehow escape away into other regions; and that the masses of air which flow outwards on all sides from the region of high normal pressure must have their place taken by fresh accessions of air poured in from above. Keeping in view the law of the barometric gradient as applicable to all heights of the atmosphere, it is evident that the ascending current from a low-pressure area, the air composing which is relatively warm and moist, will continue its ascent till a height is reached at which the pressure of the air of the current equals or just falls short of the pressure over the surrounding regions at that high level. On reaching this height, the air, being no longer buoyed up by a greater specific levity than that of the surrounding air, ceases to ascend, and thereafter spreads itself horizontally as upper currents towards those regions which offer the least resistance to it. The overflow of the upper currents is thus in the direction of those regions where pressure at the time is least, and this again we have seen to be towards and over that region or those regions the air of which in the lower strata of the atmosphere is colder and drier than that of surrounding regions.

The broad conclusion is this: the winds on the surface of the globe are indicated by the isobaric lines showing the distribution of the mass of the earth's atmosphere near the surface, the direction of the wind being from regions where pressure is high towards regions where pressure is low, in accordance with Buys Ballot's law. On the other hand, the low-pressure regions, such as the belt of calms in equatorial regions, the interior of Asia in summer, and the north of the Atlantic and Pacific in winter, with their ascending currents, and relatively higher pressure at great heights as compared with surrounding regions, point out the sources or fountains whence the upper currents flow. From these sources the upper currents spread themselves and flow towards and over those parts of the earth where pressure is relatively low. These directions are, speaking generally, from equatorial to polar regions; but more particularly towards and over those more restricted regions where in the lower strata of the atmosphere the air is colder and drier than in neighbouring regions, such as the Atlantic between the United States and Africa in summer, and Central Asia in winter.

This view of the general movements of the upper currents of the atmosphere is in accordance with the observations which have been made in different parts of the globe on the motions of the cirrus cloud, and with observations of the directions in which ashes from volcanoes have been carried by these upper currents. In further corroboration of the same views, reference may be made to the researches made in recent years, particularly by Prof. Hildebrandsson and Clement Ley, into the upper currents of the atmosphere, based on observations of the movements of the cirrus cloud in their relation to the cyclones and anticyclones of north-western Europe.

An important bearing of cyclonic and anticyclonic areas on the distribution of temperature may be here referred to. The temperature is abnormally raised on the east side of cyclonic areas and abnormally depressed on their west sides; but, on the other hand, temperature is abnormally raised on the west sides of anticyclonic areas, and depressed on their east sides—the directions being reversed in the southern hemisphere.[1] Since the temperature is lower in the rear than in the front of a cyclone, it follows that, relatively to the sea-level pressures, pressure will be lower in the upper regions in the rear of a cyclone than in front of it, a result which the Ben Nevis observations strongly confirm. Hence relatively warmer and moister upper currents will flow backward over the colder and drier air immediately in the rear of the centres of cyclones; and upper currents also presenting contrasts of temperature and vapour will overlap the outskirts of anticyclones. These considerations suggest how very diverse interpretations of the movements of the cirrus cloud in their relation to cyclones and anticylones have originated, and may also indicate lines of research into some of the more striking optical scenic displays of the atmosphere.

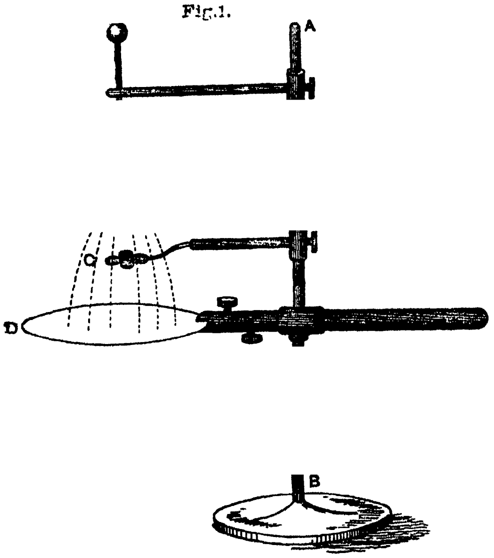
ELECTRIC SHADOWS

THE brilliant researches of Crookes upon the electric discharges in highly attenuated vacua, which some four years ago culminated in the discovery of the phenomena of "radiant matter," revealed, amongst other singular and curious effects, the existence of electric shadows. In the tubes employed by Crookes, wherein the rarefaction had been carried to millionths of the normal air pressure, objects cut out in sheets of metal or other good conductors of electricity were found to cast shadows against the glimmering surfaces of the glass when interposed in the path of the discharge. The deflection of these shadows by the magnet was also observed by Crookes. About eighteen months afterwards some analogous phenomena were observed and described by Prof. W. Holtz of Berlin; the main difference between the phenomena observed by Crookes and by Holtz being that in the experiments of the latter the shadows were obtained at the ordinary pressure of the air by means of the discharge from a Holtz's influence machine. Of these researches some account was given at the time in NATURE (vol. xxiv. p. 130) by the writer of this article. It will be sufficient here to recall the more salient points. In the place of the usual discharging knobs of the Holtz machine were fixed a wooden disk covered with silk on the one side, and a metallic point on the other. The discharge from the latter causes the surface of the former to assume a faint, phosphorescent glow, visible only in complete darkness; and on this faintly illuminated surface shadows were cast when conducting bodies—such, for example, as crosses or rings cut from thin brass or foil, strips of damp cardboard, wires, and other similar objects. It was also noticed by Holtz that these shadow-figures could be temporarily fixed by dusting upon them some fine powder, such as lycopodium. In preparing the notice of these researches for NATURE in 1881, I made the following remark:—"These dust-figures have an obvious relation with those obtained by Wiedemann from the discharge of Leyden jars through a pointed conductor against the surfaces of various bodies. It would be interesting to ascertain whether by this process also shadow-figures can be produced." The suggestion then thrown out has not been lost, for during the current year a memoir has appeared on the subject of electric shadows from the pen of Prof. Augusto Righi, of Padua, giving the results of an investigation of shadows produced by this very method. I propose to give here a *résumé* of the phenomena observed by Righi.

Fig. 1.



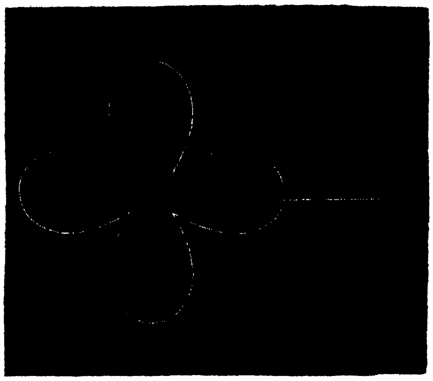


Fig. 2.

Righi discusses in an introductory way the suggestion of Crookes as to the relation between the length of the mean free path of the molecules and the distance to which the "radiant" discharge can be traced from the electrode. He observes that even in cases where the mean free path (as determined by the temperature of the gas) be very short, as in air at ordinary pressure, the motion of the gaseous molecules as a whole may yet be in nearly straight lines of considerable length, owing to the fact that the electric force in the space where discharge is taking place will necessarily tend to urge an electrified molecule along the lines of electric force, and will act in the same direction whether the charge on any single molecule remain upon it or whether it be shared with other molecules against which it may impinge in its

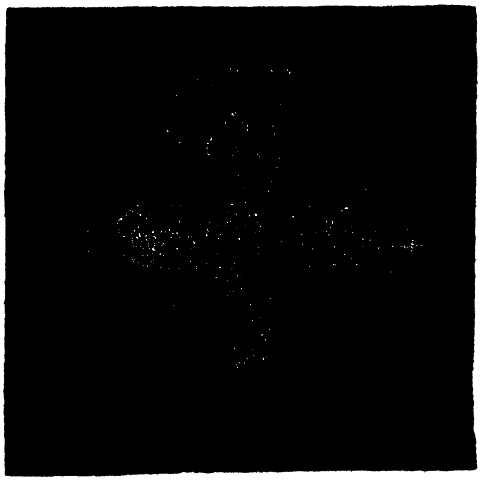

Fig. 3.

flight. The only question was whether the velocity impressed by the electric action could be made relatively sufficiently great. This depended upon the magnitude of the electric density at the surface of the electrified body, and for this reason Righi used a very sharp point for the discharge. Fig. 1 shows the arrangements for obtaining the electric shadows by Righi's process. A B is an ordinary retort-stand of iron, and upon it are clamped three adjustable arms of ebonite. The uppermost of these carries a short metal rod, pointed below and terminated above in a metal ball. The intermediate support carries the object, C, which is to cast the shadow. The lowermost arm is fashioned as a clip in which can be held a disk, D, to receive the shadows. This disk is preferably of ebonite backed on its under side with brass or tinfoil. In certain cases a metal disk varnished on the upper surface is used. Fig. 2 shows a favourite form of object for casting a shadow—a floral or cruciform design cut from thin metal and mounted on a stem of ebonite or glass. To produce the shadow-figures a Leyden jar is charged to such a potential as to be able to yield a spark of 1 to 2 centimetres' length. The outer coating is put in communication with the lower surface of the disk D, and the knob of the jar communicating with its inner coating is then brought into contact with the top of the pointed rod. The jar discharges itself rapidly and almost noiselessly. Then there is immediately sifted over the disk, from a box covered with muslin, some mixed powders of minium and flowers of sulphur, in the usual manner of procuring Lichtenberg's figures. A shadow of the interposed object is at once revealed by the powders. If the discharge has been a positive one, the shadow of the cross will appear in red surrounded by a neutral region, outside which there will be a region tinted yellow with sulphur. The colours will be reversed with a negative discharge. The shadow is depicted in Fig. 3. The size of the shadow varies with the distance of the object. Righi recommends that the object should be three centimetres above the disk, and the point twelve centimetres, or less, above the object. The lines of discharge appear to be hyperbolic in form. If a disk of ebonite only be placed at D, and the brass disk below it be lowered down, the effects are less distinct. If a narrow strip of foil or thin brass be placed below the ebonite disk, the shadow becomes compressed laterally and shows itself only on the region over the strip, and takes the form shown in Fig. 4. Similar shadows can be obtained according to Righi, on metallic disks covered with non-conducting varnish, but in this case by the use, not of the Leyden jar, but of an influence machine. This method is identical with one of Holtz's suggestion. Righi also finds that if the metal disk be previously coated with a conducting powder, such as finest zinc filings, minium, or even powdered glass, a shadow can be obtained. This method affords indeed very sharp shadows, so that thin wires and even wire gauze can be projected in shadow on the disk. Righi has gone still further, and by substituting a sensitive gelatino-bromide plate, has photographed the shadows produced during a five or ten minutes' discharge. In this experiment two figures showed themselves: one, the genuine electric shadow; the other, the genuine photographic shadow cast by the opaque object under the faint star of light emanating from the electrified point above.

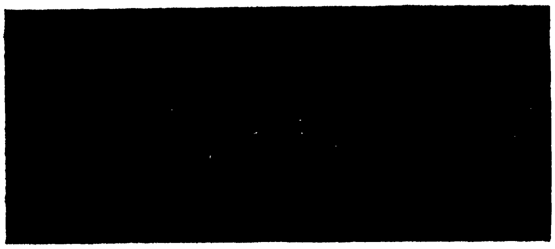

Fig. 4

If the object whose shadow is to be thus obtained is itself electrified, a curious effect is observed. If it be electrified with a charge of the same sign as that of the point above it, the shadow swells out. If electrified with a charge of opposite sign, the shadow becomes attenuated. Connecting the object to earth has the same effect as in the latter case. The presence of an electrified body on the right or left of the region in which the discharge is taking place has the effect of causing the shadow to be displaced. In fact the presence of such a body alters the equipotential surfaces, and therefore alters the lines of electric force in the field. If the discharge takes place through two points placed side by side at a short distance apart over two objects respectively beneath them, the two electric shadows are mutually repelled from the positions where their geometrical shadows lie. Similar observations of electrostatic influence were made two years ago by Messrs. Fine and Magie of Princetown, New Jersey.

Much as has been done of late years, especially by the late Mr. Spottiswoode in conjunction with Mr. J. F. Moulton, by Drs. De La Rue and Hugo Müller, by Crookes, by Goldstein, and others, to elucidate the phenomena of electric discharges, there probably still remains much to be discovered, and to be explained. The phenomena of electric shadows are amongst the matters best worthy of study in this rapidly progressing department of science. SILVANUS P. THOMPSON

NOTES

WE give this week a further instalment of notices of the strange coloured effects recently observed in the skies, and our readers in all parts of the world will render a service if they will communicate any similar facts they may have observed, giving, as far as possible, accurate dates. In an article in Saturday's *Times*, Mr. Norman Lockyer shows that the body of evidence already to hand connects them with the eruption of Krakatoa but, to place the matter beyond doubt, further information is required. The study of direction and of dates, and the facts touching the variation in the phenomena from August to December, all point in the same direction.

No one will be surprised, though all must regret, that his state of health and advanced years have compelled Prof. Owen to resign his appointment as Superintendent of the Natural History Department of the British Museum. Prof. Owen's preeminent services to science, pure and applied, are too well known to require recapitulation in these columns, especially as very recently we referred to them in detail in connection with his portrait as one of our "Scientific Worthies." Advanced in years as he is, the venerable naturalist's interest in science seems as strong as ever; to each of the last two meetings of the Royal Society he contributed an important paper: we hope they will be by no means the last of such contributions.

WE learn with the greatest pleasure that Prof. Sylvester has been appointed to succeed the late Prof. Henry Smith in the Savilian Chair of Geometry at Oxford. No more worthy successor to the late Savilian Professor could have been found, and it is satisfactory to know that at last the services of one of our greatest living mathematicians have been permanently secured for his native country.

THE ceremony of distributing the prizes to the successful students of the Finsbury Technical College and the South London Technical Art School took place on Monday evening in the Hall of the Clothworkers' Company, Mincing Lane. The Lord Mayor presided, supported by the President of the Royal Society, the Sheriffs, Sir

F. Bramwell, Sir F. Abel, the newly-elected chairman of the Society of Arts, and a large number of gentlemen interested in promoting technical education, the hall being filled with students. The prizes were delivered by Prof. Huxley, who afterwards gave an address. After speaking of the progress in technical education which had been made since 1877, and speaking in high terms of the system pursued at the Finsbury Technical College, Prof. Huxley said that all his life he had been trying to persuade people that if they wanted to teach physical science it was no use to attempt to proceed by filling the minds of the students with general propositions which they did not understand, from which they were to deduce details which they comprehended still less. If they went to the Exhibition Road, South Kensington, they would see a very splendid pile of buildings which had already cost 75,000*l.*, and which he sincerely trusted would cost a very great deal more. That building was the mere bricks and stones of the Central Institute, and the business upon which Sir Frederick Bramwell, the Chairman of the Committee, he (Prof. Huxley), and his colleagues had lately been so largely occupied was making a soul for this body. It was an immensely difficult operation, as they were always in danger, like Frankenstein in the story, of making something which would eventually devour them instead of being useful to them. Their great anxiety had been to make it good and useful, so that the great scheme of technical education might be thoroughly carried into effect. He was perfectly sure that they had in the system of technological examination, and in such institutions as Finsbury College, the Kennington School, and the Central Institution, something which would most indubitably be the nucleus of a vast growth of similar organisations. He had not the smallest doubt that, before this generation had passed away, instead of 150 centres at which such examinations were conducted, they would be counted by hundreds, and instead of the two or three high-class places of technical instruction which had been enumerated they would be counted in different parts of this island by the score, and that they would have in the Central Institute the great uniting point for the whole of this network through which the information and the discipline which were needful for carrying the industries of the country into operation would be distributed into every locality in which such industries were carried on. He regarded it as even a more important function of such organisations that they would be places to which every young artisan of industry and ability could look to gratify his legitimate ambition. His study of history had led him to the conclusion that there never had been, and there never was likely to be, any great cause of widespread social discontent except hunger of some kind or other. There was physical hunger of the body, and there was intellectual hunger arising in the minds of capable and energetic men who were prevented by the accidents of life, or the organisation of society, from taking the places for which they were fitted. Everything which spreads a knowledge of technical processes among our industrial classes tended to fit them to fight better that great battle of competition in which they had hitherto maintained themselves victoriously in virtue of the inward natural powers and capacity of the race, but in which the struggle became more difficult, not only because on the continent of Europe training and discipline were supplementing whatever might be lacking of energy and capacity, but because on the other side of the Atlantic there was a people as numerous as ourselves, of the same stock, blood, race, and power, who would run us harder than any competitors had hitherto done. If we were to hold our own in this great world competition, it must be because the native force and intelligence were supplemented by careful training and discipline, such as were proposed to be given by the system of technical education.

At the meeting last week in connection with the memorial to the late Mr. Spottiswoode, a committee was formed for the purpose of procuring a portrait or bust for presentation to the Royal Society, and also to consider the question of establishing a further memorial of his connection with the Society. Prof. Huxley, Mr. W. De La Rue, Mr. Bowman, Dr. Evans, the Astronomer-Royal, and Mr. F. Galton, were appointed as members of the committee.

We have received from the publishers, Messrs. De la Rue and Co., a sample of their pocket-books, date cards, and pretty Christmas cards, which each year seem to become more and more attractive. The pocket-book, a *spécialité* which Messrs. De la Rue have brought to great perfection, is indeed a *multum in parvo*. Not only does it contain the usual almanac, but also much useful information. The mean time of high water in all parts of the world, the length of a degree of latitude and longitude, a table of magnetic elements, which, as inferred for next year, are declination 18° 12′ W., inclination 67° 32′, horizontal force 3·92, vertical force 9·50, total force 10·27, a table of specific gravities, the various tables of weights and measures together with the French measures, the dates of eclipses, and the mean time of the sun's southing, &c., all given with the usual exactness which has caused this pocket-book to be looked to by many scientific men as a help in their daily work. The date cards are in all shapes and sizes, for hanging on an office wall or to stand on the writing table in the study. The Christmas cards are now produced with such care in drawing and colour as to have become veritable works of art, and it is truly a difficult task to select from amongst the different series before us those which may be considered to carry off the prize. Mention must, however, be made of the beautiful etchings on satin and the coloured drawings of child and bird-life, the latter particularly showing both artistic and scientific knowledge, and it was a happy thought to produce these on such a material as satin, which gives a wonderful softness and finish to the pictures, and makes them suitable for adorning screens, panels, sachets, and the various dainty trifles which will be eagerly sought for this Christmas. The hunting series is drawn with great spirit, and many a child, both old and young, will be charmed with the novel idea of the introduction of the persistence of vision by building up a hunting scene by the hunters and hare on one side and the horses and dogs on the other of a rapidly spun card. Other cards too are arranged to introduce Wheatstone's principle of the wheel of life. The flower series, which is drawn with the same delicacy that we noticed in the colouring of the birds' plumage, is this year enriched by some Alpine favourites, which will carry many of us back to our summer haunts, and cause us to thank Messrs. De la Rue for enabling us to recall at this inclement season one of the many enjoyments of our yearly holiday.

The *Times* of Friday last contains an account of the results obtained in the *Dacca* and *International*, which were sent out to take soundings in the Atlantic for the purpose of laying a cable between Spain and the Canaries. Mr. Buchanan accompanied the expedition, and his observations on the corals, which seem to be creating a "coming Atlantis," are of much interest. The precise information obtained about some of the banks which stud this part of the Atlantic is a valuable addition to existing knowledge on the subject.

The naturalist Petit has returned to France from the Congo region, where he has spent several years, especially between the Gaboon and the Congo. He brings home large collections, especially in ornithology.

One necessary result of the scattered population of the United States of America has been the co-education of the sexes. Other countries have inquired as to the effect of the mixing together of boys and girls not only in schools but also in classes, and this has led the Bureau of Education to take the opinions of the school officers of 144 towns of less than 7000 inhabitants, and 196 larger cities, as to the good or evil result therefrom. There is an almost uniform reply in its favour. Only 19 out of the whole number separate the sexes, and only 12 out of these speak decidedly against it. The general morality and tone of society in America prevent its having any mischievous effect, while their innumerable small schools necessitate a large supply of female teachers who are the better qualified by their early competition and parallel education with boys. The Bureau, however, calls attention to the fact that both advantages may be absent in an older and more thickly populated country where concentration and division of labour is more practicable.

THE Report of the Manchester Public Free Libraries is a very satisfactory one, showing that since 1876-77, when the issues of books had been decreasing for several years, a steady revival has set in and their circulation has increased more rapidly than the population. Nothing also speaks so well for the successful work, present as well as prospective, of both central and district libraries as the new catalogues of first one and then another which have followed each other at average intervals of six months only.

ON November 22, at about 9 a.m., a remarkable phenomenon was observed at Alfta in the province of Helsingland. The weather was mild and calm, and the sky clear, when from the north the rays of an aurora began to develop, and soon bathed the northern heavens. Down by the eastern horizon a heavy dark cloud rested, from which a magnificent meteor suddenly darted forth. It traversed almost the entire heavens, spreading a deep lurid light over every object, before which even the aurora paled. The simultaneous observation of a starlight sky, a flaming aurora, and a splendid meteor in the depth of winter is described as very striking.

THE *Revue Positive*, which has been edited by the late M. Littré, and latterly by M. Wirouboff, has published its last number. The reason alleged is the want of interest now felt in France for merely theoretical questions, and the success obtained in a number of special directions by the principles of positive philosophy. It has lived fifteen years.

PART III. VOL. II. of the *Memorie della Società Geografica Italiana* is entirely occupied with the working out of the zoological collections made during the Italian Expedition to Equatorial Africa. Signor Vinciguerra treats on the freshwater fishes, M. A. de Bormans on the Orthoptera, M. C. Oberthür on the Lepidoptera, and M. Lethierry on the Hemiptera; in all cases there were new forms to describe, and the most interesting Lepidoptera are illustrated on a large folded plate. These memoirs appeared originally in the *Annali del Museo Civico di Storia Naturale di Genova*, but will be useful in their collected form.

EARTHQUAKES are reported (1) from Steinbruck (Styria), where a severe shock was felt on November 7 at 3 p.m., and a second one six minutes later, both in a vertical direction; (2) from Kaltenbach, near Müllheim, where a loud subterranean noise was heard, accompanied by a shock on November 11 at 9 p.m. The phenomenon was also observed in the surrounding villages, and was preceded in the daytime by a severe thunderstorm; (3) from the neighbourhood of Trawnik (Bosnia), where, on November 15 at 9.45 p.m., a violent undulatory earthquake was felt, accompanied by subterranean noise. The phenomenon lasted five seconds, and its direction was from north-west to south-east. An earthquake is also reported from Patra (Greece), where a violent shock occurred on November 14 at 3.40 a.m.

IN connection with the Quekett Microscopical Club, six demonstrations upon elementary subjects connected with microscopy will be given at University College, in Class Room No. 8, at 7.30, on the following evenings:—December 14, 1883, Cutting Sections of Hard Tissues, by T. Charters White, M.R.C.S.; January 11, 1884, Microscopical Drawing, by J. D. Hardy; February 8, the Sponge Skeleton as a means of recognising Genera and Species, by J. G. Waller; March 14, How to Work with the Microscope, by E. M. Nelson; May 9, Polarised Light, by Charles Stewart, F.L.S.; June 13, Staining Vegetable Tissues, by W. H. Gilburt.

ON the Zuiderzee interesting experiments were recently made with fog-horns of a novel construction. They are sounded by steam, and are worked after the fashion of Morse telegraphs with long and short sounds. Two ships were provided with the fog-horns; on each there were telegraphists working the horn, and the signals were distinctly heard and understood even if the distance between the ships was such that they lost sight of each other.

A GERMAN Meteorological Society was founded at Hamburg on November 18 last, when many eminent men of science were present. Dr. Neumayer was elected president; the object of the Society was defined as—"The cultivation of meteorology as a science and in its relations to practical life." The Society will support meteorological research and publish a meteorological serial. At the first meeting Dr. Hellmann spoke on twilight phenomena, Dr. van Bebber on barometrical minima with erratic movement, and Dr. Köppen on his method of testing the results of weather forecasts.

THE additions to the Zoological Society's Gardens during the past week include two Lesser White-nosed Monkeys (*Cercopithecus petaurista*) from West Africa, presented respectively by the Rev. W. C. Willoughby and Mr. S. E. Sims; twenty Barbary Turtle Doves (*Turtur risorius*) from India, presented by Mr. A. T. Hirsch, F.Z.S.; two Bearded Titmice (*Panurus biarmicus*), European, presented by Mr. H. D. Astley, F.Z.S.; a Water Rail (*Rallus aquaticus*), British, presented by Mr. E. G. B. Meade Waldo; an Indian Crocodile (*Crocodilus palustris*) from India, presented by Sir Joseph Fayrer, K.C.S.I., F.Z.S.; two Scaly-breasted Lorikeets (*Trichoglossus chlorolepidotus*), from New South Wales, a St. Thomas's Conure (*Conurus xantholæmus*) from St. Thomas, West Indies, four West African Love Birds (*Agapornis pullaria*) from West Africa, two Undulated Grass Parrakeets (*Melopsittacus undulatus*), a Cockateel (*Calopsitta novæ-hollandiæ*) from Australia, two Indian Crocodiles (*Crocodilus palustris*) from India, deposited; a Hairy Porcupine (*Sphingurus villosus*) from Brazil, on approval; two Cirl Buntings (*Emberiza cirlus*), British, purchased.

OUR ASTRONOMICAL COLUMN

ENCKE'S COMET.—On October 16 M. Otto Struve presented to the Imperial Academy of Sciences of St. Petersburg a new memoir on the motion of Encke's comet, by Dr. Backlund, of the Observatory at Pulkowa, who has continued the researches commenced by the late Dr. von Asten. Shortly before the decease of the latter, in August, 1878, he had completed a memoir upon this comet, in which it was proved that the appearances between 1819 and 1858 might be comprised, so to say, under a single formula, adopting one value for the effect of a resisting medium; or an acceleration of 0″·104 in the mean motion in each revolution. Nevertheless the observations at the different returns were not represented with such a degree of precision as to exclude a probable error of 9″·0 for each co-ordinate of a normal position, and for certain appearances the agreement with the formula was so little satisfactory that a suspicion arose of the existence, besides gravitation and a resisting medium, of other agents which had affected the motion of the comet. The suspicion was further increased when it was found by Asten that the appearance in 1871 could in no way be included under the general formula, without admitting that the resisting medium had ceased to operate, or that the comet during the revolution immediately preceding had undergone a sudden retardation through the intervention of some unknown force. Following up at first the latter hypothesis, he was able to assign approximately the time when such perturbation must have taken effect, and found that at this time the comet was traversing the region of the small planets between Mars and Jupiter. This circumstance led Asten to conjecture that the attraction of one of these bodies, which the comet had encountered, might have occasioned the retardation.

A similar retardation was indicated again by the last appearance of the comet in 1881, and, following a similar method, Dr. Backlund was able to fix the time and the approximate place, which was again found to be in the midst of the zone of small planets. Thus, as M. Otto Struve remarks in his report upon Dr. Backlund's memoir, there was reason to think that we were upon the traces of a very interesting discovery, which added much to the interest attaching to his new researches on the last four appearances of the comet, as a complement to the investigations of Asten for the period 1819-1868. This additional work has not, however, led to a confirmation of the above-named hypothesis, but has replaced it by results of a more positive character and of greater scientific importance.

Dr. Backlund had found, on following rigorously the rules of calculation adopted by his predecessor, that the last four appearances, and particularly those of 1871 and 1881, could not be represented without admitting that the acceleration had diminished considerably, and had even disappeared for the last two returns. But on a closer examination it was discovered that a strange error had entered into the combination of the appearance of 1868 with the two preceding ones; in one of these revolutions where the observations made after perihelion were combined with those made before the succeeding one, Asten, though he supposed he had taken into account the resistance, had in fact not done so. This being rectified, the errors of 1871 and 1881, which amounted to many minutes, were destroyed in great measure, and the discordances reduced to tolerable though still unsatisfactorily large quantities. After a revision of the formulæ employed, Dr. Backlund succeeded in reducing the probable error remaining in each co-ordinate of a normal position to 4″·1. The introduction of the mass of Jupiter, according to the determination of Bessel-Schur, further reduced this probable error to 2″·8, assigning for the acceleration during the period in question 0″·054 for each entire revolution, and M. Struve considers that Dr. Backlund's researches have thus put us in possession of a theory of the comet for its later returns which leaves little or nothing to be desired.

It has been mentioned that for the period 1819-1868 the probable error in the normal positions given by Asten amounted to 9″·0. Partly, perhaps, the larger error is attributable to the inferiority of the instrumental means available in the first half of the century, but probably in a greater degree to imperfections detected in the theory adopted for this earlier period, upon which M. Struve's report enters into some detail. For this reason Dr. Backlund has charged himself with the construction of a new theory for the interval 1819-1868, in which he will be much assisted by the earlier work of Asten, described as having been left in admirable order, and thus admitting of being followed and verified at every step.

While awaiting the results of these further investigations, M. Struve draws attention to a very singular fact, which will not be affected by them. He remarks there is no reason to doubt that the acceleration has much diminished in the interval between the mean epochs of the two periods referred to above. He asks: Is it that the volume of the comet has diminished in the interval? The observations afford no trace of such diminution. Or again,—has the matter of which the comet is composed been increased? On this we can say nothing. There is, further, the supposition that the so called resisting medium has altered in density, or again, that the acceleration attributed to the effect of a resisting medium is produced by forces of a totally different nature.

All this for the moment must remain enigmatical, but the fact is established that the acceleration has diminished; we cannot say whether this diminution has been produced instantaneously or gradually; it is a point upon which the new researches undertaken by Dr. Backlund may enlighten us.

Encke's comet returns to perihelion in March, 1885.

GEOGRAPHICAL NOTES

THE eleventh number, 1883, of Petermann's *Geographische Mittheilungen* opens with a minute account of the archipelago of Chiloe, by Dr. C. Martin, who in former numbers of the *Mittheilungen*, in the *Revista cientifica de Chile*, and in other publications, has already communicated important information on this part of the earth's surface. The present contribution has special reference to vol. viii., recently published at Santiago, of the *Anuario de la Marina de Chile*. The next article gives an interesting sketch of the progress of the knowledge of Kafiristan by Europeans from 1829, when it first became known to Elphinstone, down to the present year, when Mr. McNair, the Indian Government surveyor, penetrated as far as the Dorah Pass; and an account of the present state of the inhabitants ethnographically, ethologically, socially, morally, and religiously, according to the reports of the Rev. Mr. Hughes and other recent visitors. The third article traces the route of the Russian Embassy of 1878-79 through Afghanistan and the Khanate of Bukhara, following the descriptions of Dr. J. Jaworski, member of the Russian Geographical Society, who as physician accompanied the Embassy, and has recently published an account of the expedition in two thick octavo volumes in Russian. In a long paper illustrated by a map by Bruno Hassenstein, which also embraces Dr. Junker's expedition through those parts, Dr. Emin-Bey prosecutes his travels to the west of the Bahr-el-Jebel in October and November of last year. Starting from Bedden, on the White Nile, on October 9, he penetrated south-westwards as far as Janda, the extreme southern post in the Kakuák country, whence he proceeded north-westwards through the Fadjelu Land, the station Kabajendi, the region of the Makraka and of the Abuka, as far as the station of Gosa. From this point Dr. Emin-Bey turned south-eastwards through the Abukaja country, and the Makraka-Ssgaïre stations, and on November 26 arrived at the station of Wandi. The Makraka are described as a people dowered, both men and women, with a remarkable profusion of hair, which by means of fat, the sap of trees, &c., they studiously arrange in plaits, pigtails, &c., producing very surprising effects. The name Makraka, though now universally applied to the people of that region, was, it appears, not the original name, but, signifying cannibals, was at first used by the natives to designate a body or invaders of the Iddo race from the south. Dr. K. Zöppritz, in the next following article, discusses Dr. Emin-Bey's measurements of heights and atmospherical pressure at Lado.

WE have also received the *Mittheilungen* of the Geographical Society in Hamburg for 1880-81. It contains a very copious account of the Island of Chios (or Scio) geographically, geologically, ethnologically, and commercially; a lecture on the cola-nut, delivered before the Geographical Society of Hamburg on January 5 of last year, and an instructive description of the "sacred" Japanese town of Kioto. Next follows a very careful and comprehensive account in 250 pages, by Dr. H. Sieglerschmidt, of the results of the North Polar expeditions of this century. After summing up our knowledge of the North Polar regions in the year 1818, the review traces the history of North Polar investigation since that date, taking stock, in particular, of our knowledge of East Greenland, Spitzbergen, the Siberian glacial sea, and other hyperborean tracts. Lastly, it draws up the total results down to the present date in respect of hydrography, meteorology, magnetism, astronomy, &c. In the next article Herr E. R. Flegel gives the first of a series of sketches intended to comprise (1) the mangrove swamps of the delta of the Niger; (2) the mountains of Cameroon; and (3) the banks of the lower Niger. In this first sketch we are introduced to the long and narrow sandy strip of land rising but little above the level of the sea, and running parallel with the coast of the Bight of Benin.

THE *Verhandlungen* of the Berlin Geographical Society, Band x., No. 7, contains a very copious article on Wisconsin; and the *Zeitschrift* of the same society, No. 105, gives the conclusion of Dr. Richthofen's account of his travels in China, as also, among other valuable papers, a contribution to the ethnography of the extreme north-east of Asia, by Herr G. Gerland.

WE have further received the *Bulletin de la Société de Géographie* for the second and third quarters of this year. An article by M. Grandidier briefly describes the province of Imerina, the central, as also the most populous and important, province of Madagascar. The province is mountainous, traversed by numerous water-courses, entirely bare of tree or shrub, or often even of cultivated plant, scarcely inhabited in the hilly grounds, but thickly peopled in the valleys. The hills covering most of the country, of hard and compact red clay, through which blocks of granite crop largely up, are not fertile. To the west of the capital, in the very centre of the province, is a large plain, about 30 km. long by as many broad, formerly a lake or marsh, now an immense field of rice, where emerge hamlets and houses like so many islets. There is also an interesting account of the Fuegians. The fluctuations of the Indian population in the United States are discussed by M. de Semalle in an article to which M. Simonin shortly replies. The kingdom of Perak, the Peninsula of Malacca, is described by M. De La Croix. Commandant Gallieni, of the French Naval Infantry, furnishes a mass of information on the races and populations of the Upper Niger, while Dr. Audray relates at considerable length his personal impressions and reminiscences of Hué during the eighteen months he passed there at the French Legation. M. Fernandez also communicates a paper on the Argentine Republic.

THE *Bulletin of the American Geographical Society* has a paper on the Philippine Islands by Dr. Kneeland, and another on the currents of the Pacific Ocean, by Dr. Antisell.

IN an article in the last number of the *Bremen Geographical Journal* on the inhabitants of the Chukche Peninsula, in the north-east extremity of Asia, Dr. Aurel Krause, after a brief sketch of voyages of discovery and scientific expeditions to that region, sums up the views of the different authorities with reference to the population of the peninsula, and endeavours to reconcile and supplement them with immediate observations of his own. As the result of his studies he distinguishes two different races on the peninsula—the Chukches and the Eskimo. The Chukches, again, are either nomadic or settled. The nomadic Chukches, who are also distinguished by the possession of reindeer, are scattered over the country to the west of Behring Strait, as far as Chaun Bay and the sources of the Great and Little Anjui, and south to the Anadyr River, some 5000 (German) square miles of land, with a population hardly numbering over 2000. The settled Chukches dwell on the shores of the Arctic Ocean from Chaun Bay to Behring Straits, and in some spots on the east coast in villages counting up to forty huts. There is also a third class of Chukches, intermediary between the aristocratic reindeer proprietors and the fishers, a class of merchants. A different race, looked down upon by the Chukches, occupy the south coast from Point Chaplin (or Indian Point) to Anadyr, as also parts of the east coast. That these are of the same race as the Eskimo of the opposite American coast their mode of living, their language, and bodily structure testify beyond all doubt, according to Herr Krause, his opinion on this point differing from that of the *Vega* staff. According to Dall these Eskimo are slowly drifting southwards towards Kamtschatka. The Eskimo on the Asiatic side of Behring Straits, including those of St. Lawrence Island and of the Diomedes Islands, should hardly exceed 2000. An ethnographical map and a list of Chukche and Eskimo words in connection with the Chukche Peninsula are appended to this valuable paper.

DR. EMIL RIEBECK of Halle, the well-known traveller, is preparing for a second African journey, which will be directed to the Niger. He will be accompanied by the naturalist Herr G. A. Krause, well known as an excellent linguist and mathematician.

THE NOVEMBER MEETING OF THE NATIONAL ACADEMY OF SCIENCES[1]

FOR the first time in nineteen years, and the second time in its history, the National Academy held its mid-year meeting in New Haven, November 13–16. Thirty-three of the ninety-three members were in attendance, and during its four days' session twenty papers were presented.

The meeting was conspicuous for the discussion which most of the papers called forth, and for the general participation of the members in these discussions. It was interesting also, for the report of the committee on the solar eclipse of last May, which included the detailed reports of the expedition to Caroline Island, undertaken under the auspices of the Academy, by the principal participants, Profs. Holden and Hastings. It will further be remembered by the members from other cities for the marked hospitalities they received at the hands of their *confrères* of New Haven, and for its many social pleasures, culminating in the brilliant public reception given them by the president, Prof. Marsh, at his residence. The new buildings recently finished, or in process of erection, for the furtherance of scientific research and instruction in Yale College, were also examined with interest, together with the treasures of the Peabody Museum, where the finely-mounted collections of Profs. Verrill and E. S. Dana, and the fossil vertebrates of Prof. Marsh, called forth much admiration.

The generous discussion to which the papers gave rise was provoked at the very start by the paper of Dr. Graham Bell upon the formation of a deaf variety of the human race, which had a broad, practical interest, and which consumed the entire morning session of the first day. Mr. Bell claimed that, from purely philanthropic motives, we were pursuing a method in the education of "deaf-mutes" distinctly tending to such a result, supporting his assertions by statistics drawn from the published reports of the different institutions in this country devoted to the care of these unfortunates. They are separated in childhood from association with hearing-children, and taught what is practically a foreign language—a practice which isolates them from the rest of the community throughout their lives, and encourages their intermarriage. Such marriages were increasing at an alarming ratio, and with calamitous results. As a remedy for this danger, Dr. Bell would have the children educated in the public schools, thus bringing them into contact with hearing-children in their play, and in instruction wherever they would not be placed at a disadvantage, as in drawing and blackboard exercises. He would also entirely discard the sign-language, and cultivate the use of the vocal organs, and the reading of the lips.

The report on the solar eclipse covered a variety of topics, and will fill some hundred and fifty printed pages. In presenting it, Prof. E. S. Holden merely touched upon the principal points, and gave the leading results, in much the same form as they have already been given in this journal. The objects of the expedition were successfully carried out; and Prof. Holden regarded his special work—the search for a possible planet interior to Mercury—as proving the non-existence of the small planets reported by Profs. Watson and Swift.

Dr. C. S. Hastings read in full the greater portion of his report upon the spectroscopic work, which concluded with a critical review of the generally-received theories of the solar atmosphere, and suggested, instead, that the corona was a subjective phenomenon, largely due to the diffraction of light.

The presentation of these reports occupied the entire morning session of Wednesday, and their discussion the greater part of the afternoon session.

In criticising the current use of the word "light" in physics, Prof. Newcomb opened a long and interesting discussion. He urged that photometric measurements were comparatively valueless, because they estimate a part only of the radiant energy of the sun; whereas the quantity which should be determined was the number of ergs received per square centimetre. Prof. Langley, however, asserted that it would be impossible to estimate the radiant energy received from the stars with our present appliances; not all the stars combined would produce deflection, even in so sensitive an apparatus as the bolometer.

Another feature of marked interest was Prof. Rowland's exhibition of photographs of the solar spectrum, obtained by his new concave gratings, by which he had prepared a map of the spectrum much more detailed than heretofore secured, and free from the defects of scale found in previous photographs.

Prof. Asaph Hall communicated the results of his researches upon the mass of Saturn, based upon new measurements of the distances of the outer satellites. He determines the mass of the sun to that of Saturn to be as 1 to 1/3482.

Prof. Brewer took the occasion of the Academy's meeting in the city of his residence to exhibit samples of his experiments of many years' duration upon the subsidence of particles in liquids. They showed the action of saline and organic matter, of acids and of freezing, upon the precipitation of sediments. Most of the samples had been undisturbed for five or six years, and showed varying degrees of opalescence, resulting from the suspension of matter in the fluid.

We have mentioned only the more important papers, or those which provoked a fuller discussion than usual. The following complete list will show how largely the physical side of science predominated at the meeting. In astronomy, besides the reports on the eclipse of May 6, papers were read by A. Hall, on the mass of Saturn; by S. P. Langley, on atmospheric absorption;

---

[1] *Science.* From advance sheets; favoured by the Editor.

and by O. T. Sherman (present by invitation), on personality in the measures of the diameter of Venus: in mathematics, by S. Newcomb, on the theory of errors of observation, and probable results: in physics, by S. Newcomb, on the use of the word "light"; by W. H. Brewer, on the subsidence of particles in liquids; and by H. A. Rowland, on a new photograph of the solar spectrum: in meteorology, by E. Loomis, on the reduction of barometric observations to sea-level: in geology, by T. S. Hunt, on the Animikie rocks of Lake Superior; by J. D. Dana, on the stratified drift of the New Haven region; by B. Silliman, on the mineralogy and lithology of the Bodie mining district; and by J. S. Newberry, on the ancient glaciation of North America: in chemistry, by W. Gibbs, on phospho-vanadates, arsenio-vanadates, and antimonio-vanadates, and on the existence of new acids of phosphorus: in physiological chemistry, by R. H. Chittenden (present by invitation), on new primary cleavage forms of albuminous matter: in palæontology, by J. Hall, on the Pectinidæ and Aviculidæ of the Devonian system; and by O. C. Marsh, on the affinities of the dinosaurian reptiles: and in anthropology, by A. G. Bell, on the formation of a deaf variety of the human race; and by J. W. Powell, on marriage institutions in tribal society.

The report of the Committee on Glucose, appointed by the President in conformity with a request from the Government, was accepted by the Academy, and will be transmitted to Congress with the President's report. This will also embody the proceedings of recent meetings of the Academy, the report of the Committee on Alcohol, and that on the eclipse of the sun, together with the thanks of the Academy to the Secretary of the Navy and the officers of the *Hartford* for their cooperation in the expedition to Caroline Island. It will also include an expression of the approval of the Academy of the efforts now making to secure a system of uniform time.

The next stated session of the Academy will be held in Washington in April next, and it is probable that the following mid-year session will be held in Cambridge.

RIPPLE-MARKS[1]

IN the first series of experiments a cylindrical vessel, like a flat bath, with upright sides, was placed on a table, which was free to turn about a vertical axis. Some fine sand was strewn over the bottom to a depth of about an inch, and water was poured in until it stood three inches deep over the sand. It was found that rotational oscillation with a jerking motion of small amplitude gave rise almost immediately to beautiful radial ripples all round the bath. If the jerks were of small amplitude the ripples were small, and if larger they were larger. The radiating ripples began first to appear at the outer margin of the bath and grew inwards; but the growth stopped after they had extended to a certain distance. If the jerking motion was violent, ripples were not formed near the circumference, and they only began at some distance inwards.

An analysis of the observations was made on the hypothesis that the water remained still, when the bath oscillated with a simple harmonic motion. The problem was to find whether λ, the wave-length of ripple (in inches) was directly proportional to v, the maximum velocity of the water relatively to the bottom during the oscillatory motion; also to find the values of v_1 and v_2, the least and greatest velocities of the water compatible with the formation of ripple-mark.

It appears that, for the particular sand used, v_1 is half a foot per second, and v_2 a foot per second; and that the wave-length of ripple, λ, is $\cdot 00245v$ when v is measured in inches per minute. The several results were as fairly consistent with one another as could be expected. The hypothesis that the water as a whole executes a simple harmonic oscillation relatively to the bottom is not, however, exact, and does not give the maximum velocity of the water in contact with the sand relatively thereto. The quantity called v is not in reality the maximum velocity of the water in contact with the bottom relatively thereto, but it is 6·283 times the amplitude multiplied by the frequency. Thus we cannot conclude that a current of half a foot per second is just sufficient to stir the sand. In the state of oscillation corresponding to v, it is probable that part of the water at the bottom is moving with a velocity much greater than half a foot per second relatively to the sand.

It was after making these experiments that what appears to be the key-note of the whole phenomenon was discovered.

A series of ripples extending inwards for some distance having been made by oscillation, and the water having come to rest, the bath was turned slowly and nearly uniformly round. The uniform current flattened the tops of the ripples, but made the lee-side steeper.

It was conjectured that there would be eddies or vortices on the lee-side, and in fact minute particles lying on the surface of the sand were observed to climb up the lee-slope of the ripples apparently *against* stream. This proved conclusively the existence of the suspected vortices.

If when the bath was at rest a sudden motion was given in one direction, the sand on the lee-side of each ripple was observed to be churned up by a vortex. By giving a short and sudden motion the direct stream might be seen to pile up the sand on the weather-side and the vortex to pile it up on the lee-side. The sand so displaced formed two little parallel ridges, that on the lee-side being a little below the crest of the ripple-mark.

For the purpose of examining the vortices a glass tube was drawn out to a fine point and fitted at the other end with a short piece of india-rubber tube. With this a drop of ink could be squirted out at the bottom of the water. This method was adopted in all subsequent observations, and it proved very valuable. It may be worth mentioning that common ink, which is heavier than water, was better than aniline dye.

A drop of ink was placed in the furrow between two ripples; as soon as the continuous stream passed, the ink was parted into two portions, one being sucked back apparently against stream up the lee-side of the ripple-mark, and the other being carried by the direct stream towards the crest. These points being settled, it remained to discover how the vortices were arranged which undoubtedly must exist in the oscillatory formation of regular ripples.

The observations were made in two ways, first with a glass trough so arranged that it could be gently rocked by hand, and secondly with an oscillating sheet of glass.

When the trough is half filled with water, and sand is sprinkled on the bottom, it is easy to obtain admirable ripple-marks by gently rocking the trough.

When a very small quantity of sand is sprinkled in and the rocking begins, the sand dances backwards and forwards on the bottom, the grains rolling as they go.

Very shortly the sand begins to aggregate into irregular little flocculent masses, the appearance being something like that of curdling milk. The position of the masses seems to be solely determined by the friction of the sand on the bottom, and as soon as a grain sticks, it thereby increases the friction at that place.

The aggregations gradually become elongated and rearrange themselves. As soon as the formation is definite enough to make the measurement of the wave-length possible, it is found that the wave-length is about one-half of what it becomes in the ultimate formation.

Some of the elongated patches disappear, and others fuse together and form ridges, the ridges then become straighter, and finally a regular ripple-mark is formed, with the wave-length double that in the initial stage.

If, after the formation of regular ripples, and the deposition of a drop of ink at the bottom, a very gentle oscillation be started, the layer of ink on the crest of a ripple becomes thicker and thinner alternately, swaying backwards and forwards; then a little tail of ink rises from the crest, and the point of growth oscillates on each side of the crest; the end of the tail flips backwards and forwards. Next the end of the tail spreads out laterally on each side, so that a sort of mushroom of ink is formed, the stalk of the mushroom dancing to and fro. The height of the mushroom is generally less than a millimetre.

The elongated hollows under the mushroom are the centres of vortices, and the stem is the upward current. If the ink be thick, these spaces are clouded, and the appearance is simply that of an alternate thickening and thinning of the ink on the crest. The oscillations being still gentle, but not so gentle as at first, streams of ink from the two mushrooms on adjacent crests creep down the two slopes into the furrow between the adjacent ridges, and where they meet a column of ink begins to rise from the part of the water whose mean position is in the centre of the furrow.

---

[1] "On the Formation of Ripple-mark in Sand." Abstract of a paper by G. H. Darwin, F.R.S., Plumian Professor and Fellow of Trinity College, Cambridge, read before the Royal Society on November 22, 1883.

The column is wavy, and the appearance is strikingly like that of smoke rising from a fire in still air.

The column ascends to a height of some five, ten, or perhaps twenty times the height of the ripple-marks, according to the violence of the agitation. It broadens out at the top on each side, and spreads out into a cloud, until the appearance is exactly like pictures of a volcano in violent eruption; but the broad flat cloud dances to and fro relatively to the ascending column. The ink continues to spread out laterally and begins to fall on each side. In this stage if the ink is not thick it is often very like a palm-tree, and for the sake of a name this appearance is called an ink tree. The branches (as it were) then fall on each side, and the appearance becomes like that of a beech tree, or sometimes of an umbrella. The branches reach the ground, and then creep inwards towards the stem, and the ink, which formed the branches, is sometimes seen ascending again in a wavy stream parallel to the stem.

Perhaps a dozen or twenty oscillations are requisite for making the ink go through the changes from the first growth of the tree.

The descending column of a pair of trees comes down on to the top of the mushroom, but the successful manufacture of the tree necessitates an oscillation of sufficient violence to render the simultaneous observation of the mushroom very difficult.

With violent oscillation, when the stem of the tree is much convoluted, it cannot be asserted that the mushroom vortices exist, and the author is inclined to believe them to be then evanescent.

Each side of the ink tree is clearly a vortex, and the stem is the dividing line between a pair, along which each vortex contributes its share to the ascending column of fluid. The vortex in half the tree is clearly in the first place generated by the friction of the vortex in its correlated mushroom, and is of course endued with the opposite rotation. The ascending stem of the tree is a swift current, but over the mushroom the descending current is slow until close to the mushroom, when the current is seen to be impelled by pulses.

If the adjoining crests are of unequal height, the stem of the tree is thrown over sideways away from the higher crest; and indeed it requires care to make the growth quite straight. The ink in the stem ascends with a series of pulses, and it is clear that there is a pumping action going on which renders the motion of each vortex intermittent, and the two halves of the tree are pumped alternately.

The amount of curvature in the stem of the tree depends on the amplitude of the oscillation of the water.

The ink is propagated along the convolutions of the stem of the ink tree, but the convolutions are themselves propagated upwards, and each convolution corresponds to one oscillation. The motion of the ink along the convolutions soon becomes slow, but the convolutions become broader and closer. Thus the upper part of the tree is often seen to be most delicately shaded by a series of nearly equidistant black lines.

In the transition from the mushroom stage to the tree stage it appeared that it was very frequent that only half the ink tree was formed.

If the agitation is very gentle, the sand on the crests of the ripple-marks is just moved to and fro; with slightly more amplitude, the dance is larger, and particles or visible objects, such as minute air-bubbles in the furrow also dance, but with less amplitude than those on the crests. The dance is not a simple harmonic motion like that of the main body of the water relatively to the bottom, but the particles dash from one elongation to the other, pause there, and then dash back again.

As the amplitude further increases, the furrows are completely scoured out, and the sand on the crests is dashed to and fro, forming a spray of sand dancing between two limits. With violent agitation, this dance must have an amplitude of more than half a wave-length. If the agitation be allowed to subside, the dance subsides, and when the water is still the ripple-mark is left symmetrical on both sides. With extremely violent oscillation, all the water becomes filled with flying dust, and it is no longer possible to see what is happening. This seems to be the condition when the agitation is too strong for the formation of ripple-mark. It is probable that the rush of water sweeps away the existing ripple-mark, and there is then no longer anything to produce a systematic arrangement of vortices.

The author illustrates the dance of the vortices by a succession of figures.

It is hardly possible to explain the series of changes in words, but we may here state that the mechanism by which the ripples are made and maintained depends on the fact that the upward current of a pair of vortices lingers over the ripple crest, and then darts across with extreme rapidity to the adjoining crest. Thus each pair of vortices is associated with two crests, spending nearly half the time over one, and half the time over the other.

As above stated, it has seemed that only one of each pair of tree vortices is set up at first, and the author is disposed to regard this as the transitional state from the mode of oscillation, which produces the half wave-length with small height of ripple-crest, to the fundamental wave-length with considerable height.

The results of the observations may be summarised as follows:—

The formation of irregular ripple-marks or dunes by a current is due to the vortex which exists on the lee of any superficial inequality of the bottom; the direct current carries the sand up the weather slope and the vortex up the lee slope. Thus any existing inequalities are increased, and the surface of sand becomes mottled over with irregular dunes. The velocity of the water must be greater than one limit and less than another, the limiting velocities being dependent on the average size and density of the particles. Existing regular ripple-mark is maintained by a current passing over it perpendicular to the ridges. A slight change in form ensues, the weather slope becoming less steep and the lee slope steeper. The ridges are also slowly displaced to leeward. The regular ripple-mark may also thus be somewhat prolonged, so that although a uniform current probably cannot form regular ripple-mark, yet it may increase the area over which it is to be found.

Regular ripple-mark is formed by water which oscillates relatively to the bottom. A pair of vortices, or in some cases four vortices, are established in the water; each set of vortices corresponds to a single ripple crest and the vortices oscillate about a mean position, changing their shapes and intensities periodically, but not with a simple harmonic motion.

The successive changes in the vortex motion, whilst ripple-mark is being established, and when the amplitude of oscillation over existing ripple-mark varies, are complex, and we must refer the reader to the original paper for an account of the phenomena.

It is important to note that when once a fairly regular ripple-mark is established, a wide variability of amplitude in the oscillation is consistent with its maintenance or increase. No explanation of ripple-making can be deemed satisfactory which does not satisfy this condition.

The last section gives some account of the valuable papers of MM. Hunt,[1] Casimir de Candolle,[2] and Forel[3] in this field. The author agrees in the main with these observers, but considers that some of their conclusions are open to criticism.

He next remarks that it is not easy to understand precisely the mode in which the oscillation of the water over the undulating bottom gives rise to vortices, but that there are familiar instances in which nearly the same kind of fluid motion must occur.

In the mode of boat propulsion called sculling, the sailor places an oar with a flat blade through a rowlock in the stern of the boat, and, keeping the handle high above the rowlock, waves the oar backwards and forwards with an alternate inclination of the blade in one direction and the other. This action generates a stream of water sternwards. The manner in which the blade meets the water is closely similar to that in which the slopes of two ripple-marks alternately meet the oscillating water; the sternward current in one case, and the upward current in the other are due to similar causes. We may feel confident that in sculling, a pair of vortices are formed with axes vertical, and that the dividing line between them is sinuous. The motion of a fish's tail gives rise to a similar rearward current in almost the same way. These instances may help us to realise the ripple-making vortices.

Lord Rayleigh has considered the problem involved in the oscillations of a layer of vortically moving fluid separating two uniform streams.[4] At the meeting of the British Association at Swansea in 1880 Sir William Thomson read a paper discussing

[4] "On the Stability or Instability of certain Fluid Motions." *Proc. Lond. Math. Soc.* (February 12, 1880), vol. xi. p. 57.

Lord Rayleigh's problem.[1] He showed that, in a certain case in which the analytical solution leads to an infinite value, there are waves in the continuous streams in diametrically opposite phases, and that the vortical stratum consists of a series of oval vortices. The uniform current flowing over existing ripple-mark exhibits almost a realisation of this mode of motion, one of the streams of fluid being replaced by the sandy undulations. The same kind of motion must exist in air when a gust of wind blows a shallow puddle into standing ripples.

It seems probable that what is called a mackerel sky is an evidence of a mode of motion also closely similar to that described by Sir William Thomson. M. de Candolle's suggestion that cirrus is aërial ripple-mark may then be regarded as substantially correct.

If two horizontal currents of fluid exist one above the other, the layer of transition from one to the other is dynamically unstable, but it is probable that if a series of vortices be interpolated, so as to form friction rollers as it were, it becomes stable. It is likely that in air a mode of motion would be set up by friction, which in frictionless fluid would be stable.

The formation of clouds is probably due to the saturation with moisture of one current and the coldness of the other.

The direction of striation and velocity of translation of mackerel clouds require consideration according to this theory.

It appears that if a mackerel sky be formed beween two aërial currents, the striations are parallel to that direction in which the two currents have equal component velocities, and the component velocity of the clouds parallel to the striations is equal to the component velocity of either current in the same direction.

The resultant velocity of the clouds is equal to a half of the resultant velocity of the two currents, and the component velocity of the striations perpendicular to themselves is the mean of the components of velocity of the two currents in the same direction.

The account which is given in this paper of the formation of ripple-marks shows it to be due to a complex arrangement of vortices. The difficulty of observation is considerable, and perhaps some of the conclusions arrived at may require modification. It is to be hoped that other experimenters may be induced to examine the question.

The reader is referred to the original for the figures, which are necessary to an adequate explanation of the phenomena and conclusions.

NOTE ON DEAFNESS IN WHITE CATS[2]

THIS curious occurrence has long been a matter of interest to me, originally because cats have always been very favourite pets in my household, and still more because the occurrence amongst them of deafness was used by Mr. Darwin in his first edition of "Animals and Plants under Domestication" as an illustration of correlated variability. He was under the impression that white cats with blue eyes were invariably deaf.

I had collected a number of observations which I had personally made, and I found that some white cats were deaf which had the ordinary yellow eyes, and that some white cats with blue eyes could hear perfectly well. I have never heard of deafness in any but a white cat, and all the deaf white cats I had personally examined were males. Therefore, in NATURE, 1873, I published a brief note pointing out Mr. Darwin's error. In his second edition Mr. Darwin established two cases of deafness in female white cats, so that the conclusions of both of us were upset, and this wholesale destruction of theories has been completed by the birth in one of my feline families of a white kitten, female, with perfectly yellow eyes, and absolutely deaf. She lived with us for two years, and her misfortune was quite permanent. My conclusions from the facts observed by myself now may be formulated in this way, that congenital deafness is not known to occur in any animal but the cat, though I am not quite sure but that one white mouse I had some years ago was deaf, and that no cats but those entirely white are ever deaf. As female cats are far more common than males (and this seems to be true of white cats as well as those of other colours), and as I have known only one deaf female cat for some twenty deaf males, I think I may assume that deafness is more common among males than among females. The colour of the eyes has evidently nothing to do with the deafness, though it has with the colour of the fur, and seems to be dependent on the same process—an arrest of development. The eyes of nearly all kittens are blue for some weeks after birth, and the same cause which arrests the pigmentation of the fur arrests in a very much smaller number the pigmentary growth in the eye. I have been told of two cases of complete absence of pigment in the eyes of two cats (albinism) as is seen so commonly in rabbits, guinea-pigs, rats, and mice, but I have not been able properly to authenticate them. These cats were said to be not deaf.

In 1872 I obtained a cat from Hertfordshire as an example of the polydactilism which is very common there, and when he arrived I found that he was white, that he had one eye a bright blue and the other a bright yellow, and that he was profoundly deaf. He was by far the most interesting cat I have ever possessed, and must be well remembered by many members of this Society who have favoured my house with their presence as "Old Pudge," possessed of all the feline virtues, and many of a more human type—and free from vice of every kind. He lived with us for eleven years, and died last winter of peritonitis. Whilst living with us we made many observations concerning his deafness, and I easily determined that it was purely tympanic—that is, he was deaf to impressions conveyed through the air, but his intelligence could be reached by impressions conveyed through solid media. When I wanted him to come to me I gave a peculiar sharp stamp on the floor, and he immediately responded to the signal, even if he was on a chair or table. It is very remarkable that this congenital deafness is in no way associated in the cat with mutism. Human deaf-mutes generally are those in whom deafness is cochlear as well as tympanic, and the result of such disease as scarlet fever in very early life. One other peculiarity he had is that for about four years he suffered from occasional fits of epilepsy of a very severe kind. They came on always during his sleep, and for their first indication had the painful peculiarity that the cat seized the tip of his tail and bit it off, and in this way his tail was shortened considerably. Every kind of white animal I have kept as a pet has been the subject of epilepsy, and the association is suggestive when we are told, as I have been frequently, that the disease is unknown amongst negroes.

I sent the body of my old cat to Prof. Flower for the purpose of having an investigation made into the cause of his deafness. Prof. Flower had a most careful investigation of the condition of his ears made by two most competent investigators—Dr. Cumberbatch and Dr. Heneage Gibbs. The result, briefly stated, is that all the structures in the ears were normal save the tympanic membranes, in which there were triangular gaps extending from the roof to just below the centre, the bases of the gaps being directed upwards, and their anterior side being formed by the handles of the mallei. The gaps appeared to be congenital, and were quite symmetrical; all the other apparatus of the ears was normal, and the auditory nerves were of normal size and structure.

The only congenital defect known in the human tympanum is a very minute aperture, of rare occurrence, and due to the patency of the fissure of Rivinus. The tympanic deficiency in the white cat seems to be in no way associated with this form of arrest.

The results of the observation are interesting, though the subject may perhaps be regarded as trivial, as by it the point raised by Mr. Darwin is finally established. It really is a case, and a very well marked one, of correlated variability, and its great interest is that the three structures affected—the fur, the iris, and the tympanic membrane—have a common origin from the epiblast. Had the defects observed in this cat been cochlear, the difficulty of understanding them would have been very great, as the structures of the internal ear arise from the mesoblast, according to Balfour.

LAWSON TAIT

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The recent recommendations of the General Board of Studies have all been passed. These include the appointment of a Professor of Pathology next term, of Readers in several subjects, including Comparative Philology and Botany, of University Lecturers in connection with Special Boards, including Medicine (four), Mathematics (five), Biology and Geology (six), History and Archæology (five), Moral Science (one), and of a number of Demonstrators and Assistants. Plans for new buildings for Comparative Anatomy, Botany, and Mechanism are to be obtained.

---

[1] NATURE, November 11, 1880, pp. 45-46, and see correction on p. 70.

[2] Read before the Birmingham Philosophical Society, October 11.

Dr. Besant will lecture on Analysis (Schedules II. and III.) during two terms; Mr. Pendlebury on Analytical Optics, next term, and on Laplace's and Bessel's Functions in the Easter Term; Mr. Webb on Elementary Rigid Dynamics in the Easter Term, and on Higher Dynamics in the Long Vacation.

Inasmuch as the University Table at the Naples Zoological Sation has been constantly occupied by students of animal morphology, and there are students in physiology and botany for whom study at Naples is very desirable, it is proposed to extend the advantages of study to students of biology generally. Dr. Dohrn has unofficially expressed his willingness to receive, when desired, two members of the University at a time for a payment of 100*l.* instead of 75*l.* a year.

It is hoped that the new Biological and Physical Laboratory, connected with Newnham College, which is being fitted up in Downing Place, may be ready for use by the beginning of next term. The nearness of the site to the new museums will enable students of Newnham to attend professors' lectures there and carry out practical study at the laboratory with the least possible loss of time.

With regard to the statement made last week that "St. John's does not as yet open any of its advanced lectures to other than its own students," we are informed that the advanced lectures have for a long time been open to members of the University, and lectures are provided in some subjects not lectured on elsewhere. The sentence in the report was to the effect that the list for next year was not yet issued. It has now appeared, and no less than six courses of open lectures are announced for the remainder of the academical year.

NEW ZEALAND.—The Queen has been pleased to direct Supplementary Letters Patent to be passed under the Greal Seal granting and declaring that the Degrees of Bachelor and Doctor in Science granted or conferred by the University of New Zealand shall be recognised as Academic distinctions and rewards of merit, and be entitled to rank, precedence, and consideration in the United Kingdom and in the Colonies and Possessions of the Crown throughout the world, as freely as if the said Degrees had been conferred by any University of the United Kingdom.

SCIENTIFIC SERIALS

THE *American Naturalist* for November, 1883, contains:—The Pre-cambrian rocks of the Alps, by T. Sterry Hunt.—The achenial hairs of Townsendia, by G. Macloskie.—The hibernacula of herbs, by Aug. J. Foerste.—The hair-sac mite of the pig, by Prof. R. Ramsay Wright.—The geology of Central Australia, by Edward B. Sanger.—The number of segments in the head of winged insects, by A. S. Packard, jun.

Gegenbaur's Morphologisches Jahrbuch, Bd. ix., Heft 1, contains:—Researches on marine Rhipidoglossa, by Dr. Béla Haller, No. 1 (plates 1 to 7).—On developmental relationships between the spinal marrow and the spinal canal, by Dr. W. Pfitzner.—Contribution to the comparative anatomy of the posterior limbs in fishes, part 3, Ceratodus, by Dr. M. Davidoff (plates 8, 9).—On some anatomical marks of distinction between the house dog and the wolf, by Prof. H. Landois.

Rivista Scientifico-Industriale, October 23, 1883.—On the influence of static electricity on the needle, by Prof. Michele Cagnassi.—Experiments with the radiometer (continued), by Prof. Constantino Rovelli.—On the conditions which determine the least and greatest deviation of a ray passing through a prism, by Prof. G. Buzzolini.—On the employment of copperas in testing iodides blended with alcoholic bromides and chlorides, by Dr. Alfredo Cavazzi.—On the advantages that may be derived by medical jurisprudence from entomological studies, especially in determining the approximate date and cause of death, by P. Megnin.—Note on the *Titanophasma fayoli*, a new fossil insect found in the carboniferous formations of Commentry, Allier, by the Editor.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 15.—"On *Sceparnodon ramsayi*," a fossil mammal from Australian Pleistocene deposits, by Prof. Owen. The first indication of this species was transmitted to the author, in 1881, in the form of casts of detached teeth, all representing an anterior incisor, the most entire specimen being 5½ inches in length, 35 mm. in breadth, with uniform thickness of 8 mm., the tooth, slightly curved, with persistent pulp-cavity at the base, and a sharp chisel-shaped cutting margin at the opposite end. The author deferred notice of this indication in hope of receiving a specimen of the tooth itself. This was needed in order to make the requisite microscopical researches as to structure, the wombat and some small rodents alone possessing, in Australia, ever-growing scalpriform incisors, but markedly differing in shape as well as size from the fossil. Prof. Owen was favoured by receiving, in the present year, from the bed of King's Creek, Queensland, a tooth, identical in character with the cast, and the present paper records the results of his scrutiny of structure. They led to the conclusion of the former existence in Australia of a mammal with rodent upper incisors, as in the wombat, but of distinct shape, and indicative of a species as large as a tapir. The microscopic characters of both dentine and enamel weighed in favour of the marsupial affinities of *Sceparnodon*. The author referred to the fact that the first indication of the genus *Thylacoleo* was a single carnassial tooth submitted to him in 1833 by Sir Thomas Mitchell, and a similar evidence of *Diprotodon* was an incisor brought by the same explorer from the caves he had discovered in the district named, after the Colonel's old commander, "Wellington Valley."

At the same meeting Prof. Owen gave a minute description of a fossil humerus which had been transmitted to him by Mr. Ramsay, F.L.S., who had discovered it in the breccia cave in "Wellington Valley." The bone was partially mutilated, but gave sufficient evidence of its having come from a Monotreme, with so close a conformity, save in size, with that of the existing *Echidna hyotrix*, as to lead to its reference to an extinct species of that genus. It, however, far surpassed it in size, exceeding, as it did, the corresponding bone in the larger Monotrematous ant-eaters which have been found living in New Guinea. Drawings of the subjects of both papers accompanied the text.

Geological Society, November 21.—J. W. Hulke, F.R.S., president, in the chair.—The following communications were read:—On the skull and dentition of a Triassic mammal (*Tritylodon longævus*, Ow.) from South Africa, by Prof. Owen, C.B., F.R.S. The specimen described in this paper formed part of a collection containing remains of some of the known South-African Triassic reptilian genera, and agreed with them in its mode of fossilisation. It was submitted to the author by Dr. Exton, of Bloemfontein. The specimen is a nearly entire skull, wanting only the binder part, and it measures about 3¾ inches in length, from the broken end of the parietal crest to the point of the united premaxillaries. The upper surface shows the anchylosed calvarial portions of the parietals, and the frontal bones divided by a suture; the contiguous angles of these four bones are cut off, so as to leave an aperture, occupied by matrix, which may be a fontanelle, or a pineal or parietal foramen. The frontals form the upper borders of the orbits, which are bounded in front by the lacrymal and malar bones, and were not completed behind by bone. Each frontal is narrowed to a point at the suture between the nasal and maxillary. The nasals are narrow, but widen in front to form the upper border of the exterior nostril, which is terminal, and is completed by the premaxillaries. The maxillaries are widened posteriorly, then constricted, and again widened before their junction with the intermaxillaries. The teeth include a pair of large round incisors, broken off close to the sockets and showing a large pulp-cavity, surrounded by a complete ring of dentine, which is covered by a thin coat of enamel on the front and sides. At 2 mm. behind each of these teeth is the socket of a smaller premaxillary tooth; this tooth apparently had a thin wall and a pulp-cavity relatively larger than in the anterior tooth. It is separated by a ridged diastema from the series of six molar teeth on each side, the first of which has a sub-triangular crown with the base applied to the second tooth. The latter and the four following teeth are nearly similar, subquadrate in form, with the crowns "impressed by a pair of antero-posterior grooves, dividing the grinding surface into three similarly disposed ridges, and each ridge is subdivided by cross notches into tubercles. Of these there are, in the second to the fourth molar inclusive, four tubercles on the mid-ridge, three on the inner ridge, and two on the outer ridge." The author discussed the relations of this new form of mammal, especially as indicated by the structure of the teeth, which he showed to resemble those of *Microlestes*, from the Keuper of Würtemberg and the Rhætic of Somersetshire, and those of the Oolitic genus *Stereognathus*, the former having on each tooth two multituberculate ridges, and the latter three ridges, but with only two tubercles on each. The fossil presents no characters to show definitely whether the animal it represents was a placental or a non-placental mammal.—Cranial and vertebral characters of the crocodilian genus *Plesiosuchus*, Owen, by Prof. R. Owen, C.B., F.R.S. In this paper the author, with the view of showing that the Kimmeridgian *Steneosaurus manselii*, Hulke, really forms the type of a distinct genus, discussed the characters by which Cuvier divided the fossils referred by him to the Crocodiles into three principal groups, to which Geoffroy St.-Hilaire gave generic names, and those by which the latter author afterwards distinguished his genus *Steneosaurus*, including Oolitic forms, from the Liassic genus *Teleosaurus*. From his exposition of these characters the author concluded that the above-named species does not belong to *Steneosaurus*, Geoff., and he proposed to make it the type of a new genus, *Plesiosuchus*, characterised by the convergence of the frontal bones to a point nearer the apex of the skull than in *Steneosaurus*, by the extension of the gradually attenuated nasal bones into a point penetrating the hind border of the nostril, and by other peculiarities of the skull, teeth, and vertebræ. The author pointed out that this form, like *Steneosaurus*, helped to bridge over the space between the Liassic Teleosaurs and the Tertiary and recent Crocodiles, even approaching nearer to the latter than the older Oolitic type.—On some tracks of terrestrial and freshwater animals, by Prof. T. McKenny Hughes, M.A., F.G.S. The author's observations have been made on certain pits in the district about Cambridge which are filled with the fine mud produced in washing out the phosphatic nodules from the "Cambridge greensand"—a seam at the base of the chalk marl. As the water gradually dries up, a surface of extremely fine calcareous mud is exposed. This deposit is often very finely laminated, and occasionally among the laminæ old surfaces can be discovered, which, after having been exposed for some time to the air, had been covered up by a fresh inflow of watery mud into the pit. The author described the character of the cracks made in the process of drying, and the results produced when these were filled up. He also described the tracks made by various insects, indicating how these were modified by the degree of softness of the mud, and pointed out the differences in the tracks produced by insects with legs and elytra, and by Annelids, such as earthworms. The marks made by various worms and larvæ which burrow in the mud were also described. Marks resembling those called *Nereites* and *Myrianites* are produced by a variety of animals. The groups of ice-spicules which are formed during a frosty night also leave their impress on the mud. The author concluded by expressing the opinion that *Cruziana*, *Nereites*, *Crossopodia*, and *Palæochorda* were mere tracks, not marine vegetation, as has been suggested in the case of the first, or, in the second, the impression of the actual body of ciliated worms.

Anthropological Institute, November 27.—Prof. Flower, F.R.S., president, in the chair.—Dr. J. G. Garson read a paper on the cranial characters of the natives of Timor-Laut. The osteological remains described in this paper were obtained by Mr. H. O. Forbes from the district of Larat, and consist of a series of eleven skulls and crania. The four male skulls are all of a round form, and resemble one another in general appearance; of the females, five correspond in form to the male skulls in being short and broad, but the sixth differs markedly from the others in being narrow in proportion to its length.—Mr. H. O. Forbes read a paper on the ethnology of Eastern Timor, referring especially to the great intermixture of race that has taken place, and to the occurrence of a red-haired, blue eyed race in the interior; to the numerous dialects, many of them unintelligible at a short distance from the district in which they are spoken; to the religious rites of the people of certain regions, conducted by a priest in what is called the Uma Lulik (or Taboo House) with an intricate and imposing ceremonial; to their marriage ceremonies and customs, which in some districts remind one of the Australian totem system in the occurrence of husband clans and wife clans; to their death and burial rites; to their system of law and justice, under which, though the chief was king and judge, each freeman had the right—or took it—of private war, retaliating on the wrong-doer with his own hands for loss in his property or person. "Eye for an eye" ran their code, like our own Old English one, "and life for life, or for each fair damages." Mr. Forbes had directed special inquiries into the alleged habit of the Timorese in intentionally artificially distorting their infants' heads. No such custom was found to prevail in the districts traversed by him.

The Victoria Institute, December 3.—A paper on recent Egyptological research in its Biblical relations was read. In it the author, the Rev. H. G. Tomkins, described the results up to the present of those researches which are now being made in Egypt, alluding in warm terms to the assistance rendered him in the preparation of his summary of these results by M. Naville and Prof. Maspero.

The Institution of Civil Engineers, November 27.—Mr. Brunlees, president, in the chair.—The paper read was on the new Eddystone lighthouse, by Mr. William Tregarthen Douglass, Assoc.M.Inst.C.E.

CAMBRIDGE

Philosophical Society, Nov. 26.—The following communications were made to the Society:—On the measurement of electric currents, by Lord Rayleigh. The author referred to the method of measuring currents by the silver voltameter as suitable for currents from ·05 ampere to 4 amperes, and stated that the electrochemical equivalent of silver as determined at the Cavendish Laboratory was $1·119 \times 10^{-2}$. A second method was described, suited for larger currents; it consists in balancing the difference of potential between two points in the circuit through which the current is running against the effects of a standard cell working through a large resistance such as 10 000 ohms. The author suggested as a third method the use of the rotation of the plane of polarisation of light passing through a piece of heavy glass, round which the current circulates in a coil of thick wire. A current of 40 amperes will produce a rotation of 15° if the coil have one hundred turns.—On the measurement of temperature by water-vapour pressure, by Mr. W. N. Shaw.—On some measurements of the well-known dark rings of quartz, by Mr. J. C. McConnel.—On the origin of segmentation in animals, by Mr. A. Sedgwick.

EDINBURGH

Royal Society, December 3.—The Right Hon. Lord Moncreiff, president, in the chair.—This being the opening meeting of the 101st session, it had been the intention of the President to give a Review of the Hundred Year's History of the Society; but, on account of his indisposition, the meeting permitted its postponement. Mr. Robert Gray, one of the vice-presidents, occupied the chair during the remainder of the evening.—Prof. Turner communicated a paper by Prof. Haycraft on the limitations in time of conscious sensation. The paper contained the result of experiments on the limitations in time of tactile and thermal sensations, and dealt also with the limitations in the case of the different senses.—Prof. Tait read a paper by Mr. W. F. Petrie on the old English mile. The old mile was longer than the present, and consisted of 5000 feet of 13 inches. It seemed to be identical with the old French mile. The furlong had no connection originally with the mile, which was modified to suit the former.—Mr. Patrick Geddes read a communication on the re-formation of the cell theory. In a second paper, in order to explain muscular contraction, he advanced an hypothesis based on the existence of surface tension in fluids.

DUBLIN

Royal Society, November 19.—Section of Physical and Experimental Science: G. Johnstone Stoney, F.R.S., vice-president, in the chair.—Prof. W. F. Barrett read a paper on hearing-trumpets and an attempt to determine their relative efficiency by physical means. With the view of obtaining a steady and comparable source of sound of a pitch and quality resembling the human voice, a reed pipe was inclosed in a padded box with an opening on one side, and blown by a steady current of air from a holder, a manometer showing the pressure, which was kept constant. The distance at which sound from this source ceased to be audible was noted, and in cases of slight deafness a sliding shutter was added. In other arrangements devised by the author, the principle of interference of sonorous waves was utilised, the degree of deafness being estimated by the departure from complete interference. An induction balance, in which the interrupter was a C tuning-fork, was also tried; as also a siren driven by a falling weight and blown by a current of air at constant pressure; but none of these arrangements were so simple and uniform as the reed. An attempt was made to test the value of ear-trumpets by means of a sensitive flame. The flame was, however, less sensitive than the ear to sounds of the pitch of the human voice. The author contended that the main object of a hearing-trumpet should be clearness, not loudness, and for this purpose the portable whispering tube was undoubtedly the best for conversation. For other purposes the principles laid down by Lord Rayleigh should be more generally adopted, the telescopic jointed instrument of gradual slope being the nearest approach to theory.—Prof. G. F. Fitzgerald, F.R.S., read a paper on the quantity of energy communicated to the ether by a variable current. The author shows that an alternating electric current, if it produces radiations of the nature of light, as it would do upon the most probable interpretations of Maxwell's electromagnetic theory of light, would radiate energy equal to $m^2 \times N^4 \times 10^{-29}$ ergs per second, where m is the magnetic moment of the current and N is the number of its alternations per second.—W. E. Wilson exhibited a simple form of reflecting spectroscope with a diffraction grating, which was described by Howard Grubb, F.R.S. By employing a pair of mirrors, by which the light is twice reflected, the necessity for having an instrument of inconvenient length is avoided.—R. J. Moss, F.C.S., exhibited a remarkable specimen of crystallised stibnite from Japan. The crystallographic characters of similar specimens have recently been described by E. S. Dana. Mr. Moss found that this stibnite may be regarded as practically pure antimony tersulphide; a very minute trace of iron is the only impurity present in appreciable quantity.

Section of Natural Science: Prof. V. Ball, F.R.S., in the chair.—H. St. John Brooks, M.B., read a paper on the osteology and arthrology of the haddock (*Gadus æglefinus*). The chief feature of this paper was a description of the articulations of all the bones and the attachments of the various ligaments. The author drew attention to the beautiful arrangement of the articulations of the upper jaw of fishes which is seen to great advantage in this form. Ligaments passing from the palate bones to the premaxillæ of the opposite side are crossed by others passing from the ethmoid to the maxillæ, the whole forming a lattice like arrangement. By these ligaments the component parts of the upper jaw are kept in contact with a nodule of cartilage, which lies between them and the ethmoid.—Prof. V. Ball, F.R.S., exhibited and drew attention to a conglomerate of quartz pebbles which is found at the base of the chalk in certain parts of the county of Antrim, and which appeared to him to be inconsistent with a deep-sea origin. He also exhibited bones of red deer, ox, pig, fragments of pottery and flint flakes, &c., from a kitchen midden at White Park, Bray, Co. Antrim. Among specimens recently contributed to the Geological Museum, samples of spherical phosphorite from Southern Russia were exhibited. One of them, which had been sliced, shows a beautifully radiated internal structure; this, it is hoped, will be figured and published with details shortly.—Dr. W. Frazer read a note on bones and shells obtained from drainage cuttings at Sandymount.—G. Johnstone Stoney, F.R.S., exhibited cores of limestone found in the drift overlying Cambrian slates near Greystones, Co. Wicklow. Water percolates through the drift, and, on reaching the Cambrian slates, makes its way horizontally through the lowest layer of the drift, corroding the limestone boulders, which form one of its constituents; cores of solid limestone are frequently found of some fantastic form in the heart of a friable mass which remains in the part of a boulder that has been acted on by water charged with carbonic acid. This shows that the corrosion is still actively progressing, and that the drift is here undergoing a change which is rapid from a geological point of view. The water also washes away the fine particles of clay, and the result of the change is to alter a clay drift containing a great number of limestones with some stones of other kinds into a gravel containing chiefly these other stones.—A. G. More, F.Z.S., exhibited as a specimen recently acquired by the Natural History Museum the mountain Goat (*Mazama americana*) from the Rocky Mountains. This animal is remarkable for the abundance of its soft white hair; it has the general appearance of the goat, and its horns somewhat resemble those of the chamois.

PARIS

Academy of Sciences, December 3.—M. Blanchard, president, in the chair.—Note on the universal hour proposed by the Conference in Rome, by M. Faye. The author urges several objections against the adoption of Greenwich astronomical time and meridian, calculating the longitudes from 0 to 24h. east, which might be convenient for navigation and astronomical purposes, but unsuitable for railways, telegraphs, government offices, and the public generally. For the formula, universal time = local time − (L + 12h.), where L indicates the longitude calculated east from Greenwich, he proposes to substitute, universal time = local time − L. The formula would thus be simplified by the suppression of the last term, and, instead of Greenwich astronomical time, the civil hour would be adopted as the universal hour. Thus would be avoided the inconvenience of disagreement between local and univeral time, which would otherwise be felt precisely in the most densely peopled regions of the globe.—Remarks on M. Piarron de Mondésir's so-called mechanical problem of the two chains, by M. H. Resal.—On preventive inoculation with artificially developed charbon germs attenuated by the method of rapid heating, by M. A. Chauveau. Of a large number of sheep inoculated with germs heated to + 80° C., not one succumbed, although further tests showed that the germs themselves had lost none of their prolific vitality.—Summary reports on the results of the French mission to Cape Horn: astronomial observations by M. H. Courcelle-Seneuil; terrestrial magnetism, magnetic registers, and photographic work, by Lieut. E. Payen; magnetic observations made at Orange Bay by M. Le Cannellier; *résumé* of the meteorological observations made at Orange Bay between September 26, 1882, and September 1, 1883, by Lieut. J. Lephay.—On the absorption line produced by diluted blood in the violet and ultra-violet region of the spectrum; photographic reproduction of this line in solar light, by M. J. L. Soret.—On the secular variation in the direction of terrestrial magnetic force at Paris (continued), by M. L. Descroix.—Description of an "aëroplane" constructed for the purpose of furthering aërial navigation, by M. de Sanderval.—Supplement to a previous note on M. Tisserand's formula connected with the celestial mechanism, by M. Radau.—Determination of the mutual distances of the three masse. in the mechanical problem of the three bodies, by M. A. Lindstedt.—Theory of the ricocheting action of spherical projectiles on the surface of the water, by M. E. de Jonquières.—On the theory of Abelian integrals, by M. E. Goursat.—On a theorem of Riemann connected with the functions of independent n variables admitting $2n$ systems of periods, by MM. H. Poincaré and E. Picard.—On the geometrical curve of the fourth degree with two double points, by M. Humbert.—On the integration of a homogeneous rational function, by M. C. Stéphanos.—Measurement of the difference of potential of electric layers on the surface of two liquids in conta t, one illustration (continued), by MM. E. Bichat and R. Blondlot.—On M. De·ains' optical experiment: determination of the optical constants of a birefractive crystal of one axis, by M. Lucien Lévy.—Researches on the stability of solidified superfused sulphur, by M. D. Gernez.—On the artificial production of spessartine (manganesiferous garnet), by M. Alex. Gorgeu.—Experimental researches on the development and accumulation of saccharine (the phenomenon of "saccharogénie") in beetroot, by M. Aimé Girard.—On the acetate of biprimary bichloretted ethyl $\left(\begin{matrix}\mathrm{ClCH^2-CH^2}\\ \mathrm{ClCH^2-CO}\end{matrix}\!\!>\mathrm{O}\right)$, obtained by the reaction of the monochloretted chloride of acetyl on monochlorhydric glycol, by M. Louis Henry.—On the conditions suitable for accelerating the oxidation of siccative oils, by M. Ach. Livache.—On copper as a preservative against infectious diseases, and on the absolutely harmless character of the powders of this metal employed by workers in copper, by M. V. Burq. From his further researches the author maintains, against recent statements to the contrary, that copper undoubtedly possesses certain prophylactic properties against several infectious maladies, and especially against cholera.—Construction of the scapulo clavicular cincture in the series of Vertebrates, by M. A. Lavocat.—On the sexual and larval polymorphism of the plumicole Sarcopidæ, by MM. E. L. Trouessart and P. Mégnin.—Researches on the physiological properties of maltose (continued), by M. Em. Bourquelot.—On the Adapisorex, a new genus of mammals occurring amongst the Lower Eocene formations of the neighbourhood of Reims, by M. V. Lemoine.—On the discovery of the genus Equisetum in the Kimmeridge clays of Bellême, department of Orne, by M. L. Crié.—On the quaternary lignites of Bois-l'Abbé, near Épinal, by M. P. Fliche.—On the remarkable sunsets observed at Paris and elsewhere in France on November 26 and 27, by M. L. Renou. The author considers that this phenomenon may be connected with a condition of the atmosphere which recurs on the same day every year. Electric disturbances have been regularly observed between November 26 and 28 ever since the shower of meteors, which occurred on November 27, 1872.

BERLIN

Physical Society, November 16.—The experiments with a view to determining the neutral point in the spectrum in the case of the colour-blind, which Dr. König communicated to the Society in March last, have since been further prosecuted by him. With the help of the apparatus, formerly described, consisting of a prism, a movable collimator, and a telescope directed towards the prism's edge, Dr. König had now succeeded in determining in thirteen different cases of colour-blindness the place of the spectrum at which these colour-blind persons felt the impression of white—of the place, namely, which appeared to them exactly of the same hue as would a surface covered with magnesia and shone upon by the light of white clouds. Each measurement was carried out eight times, and then the average taken, by which it appeared that the error in the single measurement was confined probably between ± 0·09 and ± 0·5 millionths of a millimetre. Measurements carried out with an individual for the second time after an interval of fourteen days, showed likewise the same exactness. In the case of the thirteen colour-blind persons who were examined, among them being both red- and green-blind, the neutral point lay between 491·7 and 504·7 millionths of a millimetre, wave-length. If the persons so examined were ranged in accordance with the wave-lengths of their neutral point, it was found that within the limits above specified they formed a fairly continuous series in which red- and green-blind persons took their places indiscriminately, a result in perfect agreement with former conclusions. In his first investigations into the subject, Dr. König had further found that the intensity of light exercised an influence on the situation of the neutral point, and had now further prosecuted this question by experiments on three individuals. For the graduation of the intensity of light he made use of two Nicol prisms in front of the collimator tube, and found, in the case of all three individuals, that with increasing intensity of light the neutral point approached closer to the violet end of the spectrum. Let the wave-length be taken as abscissa, and the intensity of light as ordinate, then would the curve of the neutral points form no straight line, and would, under great increase of intensity, mount upwards almost perpendicularly.—Prof. Schwalbe had in the summer of this year, as in former years, visited several glacial cavities, a branch of inquiry in which he particularly interests himself. In these investigations he took special note of the cold winds issuing from fissures and clefts of the places in question. At Questenberg, for example, in the Southern Harz, he found a place where from a fissure in a steep gypsum wall of about 100 feet high, and having a southern situation, a wind issued with a temperature of 3° C., while the temperature of the air immediately surrounding it was 20° C. warmer. The temperature in the stone fissures was found by him to be still lower, the thermometer often showing zero there, while in the cavities themselves the temperature he had generally observed (in July) was 5° C. Prof. Schwalbe brought out the fact of the great diffusion of such glacial cavities. Besides two in the Harz, he had this summer counted as many as twenty to twenty-five glacial cavities, mostly quite unknown hitherto, in the Karst Mountains on the southern frontiers of Carniola. With regard to the explanation of this phenomenon he still held by the view formerly set forth by him, that the cold was caused by the water which had been cooled to 4° C. filtering through the porous stone, and he deemed a resumption of Herr Jungk's experiments on the cooling of the trickling water necessary to a definite decision on the cause of glacial cavities.

Physiological Society, November 23.—In the cortex of the vertical lobe of the brain, Prof. Munk had, as is known, demonstrated that the separate groups of voluntary muscles had each of them a definite central area whence their movements could be induced. One part of this cortical area was recognised as the central seat of the muscles of the nape and neck, and after these two groups had been topically distinguished, Prof. Munk conjectured that the voluntary muscles of the larynx and jaws would be found to have their centre in the section of the membrane appropriate to the jugular muscles. Dr. H. Krause had put this conjecture to experimental proof, and found it confirmed. On bending back a dog's epiglottis and drawing forward its tongue, the larynx could very readily be observed by daylight, and when the jugular part of the cerebral membrane was irritated by moderate electrical currents, he invariably noticed the rise of the larynx, the movement of the chordæ vocales to a place situated in the middle between expiration and phonation, the rise of the palate, the contraction of the constrictor pharyngis, and movements of the hindermost parts of the tongue. That the part of the membrane in question was the centre of the laryngeal movements was further confirmed by experiments of extirpation which were performed successfully on both sides with ten dogs. The part of the membrane was experimented on in this way first on one side and then on the other, and after all inflammatory symptoms had disappeared, and the cerebral wounds were cicatrised or in process of cicatrisation, it was found that eight dogs had entirely lost the capability of barking, and, on attempting to bark, uttered either no sound or only a hoarse whine, such as new-born puppies emitted. In the case of the two dogs which after the operation continued capable of barking, it appeared that the excision had been made too far on the outside, or not deep enough. Some dogs which after the operation were no longer capable of barking were, after several days, killed, when Dr. Krause searched for the nerve passages, which, in consequence of the removal of the cortical part, were degenerated. In the *ganglion mamillare* he found a part of the nerve fibres in a collapsed, discoloured, and degenerated state, and concluded that the fibres extending from the membranous centre of the larynx to its motory nerves passed through this ganglion. At the invitation of the President, Prof. Munk gave a brief plan of the topography of the membrane of the cerebrum, on which were projected the different sensible and motory nerves of the separate parts of the body. On a drawing of the cerebral surface he showed the particular sites which were the centres of seeing, hearing, feeling, and motion for the muscles of the eyes and the ear, for the face, tongue, nape, neck with larynx and throat, and for the thorax. A particular locality was also pointed out for the muscles of expiration and for those of inspiration. The centres for the extremities had not yet been experimentally demonstrated, but no doubt they were situated on the inside in the large fissure of the cerebrum, where, on account of the unavoidable profuse bleeding which occurred, operations were impracticable.

MERRIFIELD'S "TREATISE ON NAVIGATION"

A Treatise on Navigation for the Use of Students. By John Merrifield, LL.D., F.R.A.S., F.M.S. (London: Longman and Co., 1883.)

THE author of this volume having been engaged for many years in preparing candidates for the different examinations into which navigation enters, has felt the want of a text-book embracing all that the different examining boards embody under that head, and has endeavoured, and we think successfully, to supply that want by the present treatise.

The work, although entitled "A Treatise on Navigation," deals only with one part, viz. that particularly relating to what is generally known under the name of dead reckoning, and does not touch on astronomical observation, which we presume Mr. Merrifield classes under the head of nautical astronomy, but which is really the most important part of navigation. The title therefore is somewhat misleading. Neither do we agree with the author's definition of theoretical and practical navigation; what Mr. Merrifield terms practical navigation, viz. the management of the ship, making and shortening sail, steering, &c., is usually known as seamanship. The theory of navigation is surely the proving that by the application of certain problems the particular position occupied by a vessel can be accurately ascertained; whilst the practice is the actually finding the ship's place by means of the instruments necessary to give the data required by the theory.

But although some small points in the work may be selected which may perhaps offend the practical navigator confident in his own ability, and consequently too much inclined to look down on the instructions of schoolmen, to whom he is far more indebted than he is generally disposed to admit, to the student this work will be found most useful: the chapters are well arranged, the exercises at the end of each chapter are pertinent to the preceding text, and require him to digest the text in order to answer them satisfactorily. We propose, however, to offer some remarks and suggest some additions which the author may perhaps consider should another edition of his work be required.

In the description of the compass one type only has been selected—that in use in the mercantile marine. No account is given of the instruments used in the navy or of Sir William Thomson's invention. This is certainly a defect in the work, as if one instrument can be considered as of more importance than another, in the navigation of a vessel, it is the compass. Without it, notwithstanding all the other improvements which have taken place in navigation, we should be in much the same position as the seamen of old, who were afraid to venture out of sight of land. In fact we have always thought that the education of naval men so far as regards the compass, and magnetism generally, has been very much neglected, and its vast importance has hitherto not received that attention, in treatises on navigation, it deserves. Mr. Merrifield has made a great stride in advance, as he treats, in his ninth chapter, of the coefficients and the means of correcting the compass for the local attraction of the ship. This is a subject of great importance in the present day; all navigators should be able to adjust their own compasses, and should have the means of doing so at their disposal, as a compass might be disabled in any vessel, and in war-ships, particularly, a general action might cause the loss of the correcting magnets of every vessel in the squadron, when, unless some officer on board could replace them, and correct the compasses, the fleet might be placed in a most critical position, more especially in thick weather or when entangled amongst shoals. We doubt if the latter contingency has yet excited any attention, yet its importance will be at once seen if we suppose that one ship only in a squadron has had her compass disabled in action and that subsequently thick weather prevails. Such a ship endeavouring to obey the signals of the admiral might either fall into the enemy's hands or by fouling vessels in her own squadron temporarily render them unfit to renew the engagement.

Whilst considering this contingency, it might perhaps be as well to draw attention to the fact that, in addition to our ironclads, many large steam-vessels are now fitted with sirens in place of the ordinary steam-whistle. It would therefore seem expedient that some definite means should be enforced to prevent their signals being mistaken for the sirens sounded in foggy weather from lighthouses and lightships.

In describing the mode of correcting the compass for the effect of local attraction no notice is taken of the method of doing so by a single magnet—often adopted in the navy. We are, however, glad to see that Mr. Merrifield refers the student to the works of Sir George Airy and Sir Frederick Evans, to both of whom sailors owe a debt of gratitude. That we are able to navigate our large iron ships and armour-plated vessels with the same facility as the old wooden ships of the past is due almost entirely to their labours, combined with those of the late Archibald Smith, F.R.S.

In the chapters on the various methods of finding the position of a ship by dead reckoning, known as the "sailings," we do not find much improvement on the works of the older writers except in one particular—Mercator's sailing. This, which is the most accurate method of dead reckoning, is treated of in a separate chapter, and the formula for calculating the meridional parts for the spheroid, as well as the sphere, is now for the first time published in "A Treatise on Navigation," the only work of the sort in which we remember to have seen it before being Galbraith's "Surveying." It is true that Riddle, in a note, refers the student to Gauss's paper, published in the *Philosophical Magazine* for 1828, and Mendoza y Rios, in his tables, gives the meridional parts for the spheroid as well as the sphere, but does not say what compression he used in the calculation: Mr. Merrifield, however, seems to be the first to give the subject that prominence in "A Treatise on Navigation" we think it deserves, more especially now when the steamers running from England to the United States are reaching the extraordinary rate of 450 miles a day, and it is no unusual thing to be two or three days without obtaining astronomical observations. It therefore becomes necessary to use the most rigorous means to calculate the position by dead reckoning, so that the errors of steering, &c., may not be augmented by errors in calculation. Such being the case, we regret that Mr. Merrifield has omitted from the chapter on traverse sailing the warning given in Raper that, especially in high latitudes, the differences of longitude should be found on each course, instead of the departures being lumped and the difference of longitude found from the result.

In the chapter on soundings and tides (No. 10), Mr. Merrifield has published the system of the late Sir Francis Beaufort for ascertaining the height of the tide at any moment provided we know the range and time of high water. This is the method generally adopted by surveyors when circumstances prevent their having a tide pole on shore, and is traditionally known amongst them, though not hitherto published. It is fairly accurate when the diurnal inequality is inconsiderable, and we can recommend it as being sufficient for all practical purposes in finding the depth of water to be added to the soundings on the chart in places like the Bristol and Irish Channels, where it is necessary, owing to the large ranges, to take the state of the tide into consideration in judging the position by soundings in foggy weather, or in calculating when a bank or flat can be safely crossed. The fact that in rivers or harbours certain winds affect the height and that atmospheric pressure also has an influence over tides may be safely ignored in the open sea, as their combined influence would probably never exceed half a fathom, but a range of from three to five fathoms can never be lightly considered by the careful navigator.

OUR BOOK SHELF

Farm Insects. Being the Natural History and Economy of Insects Injurious to Field Crops, and also those which Infest Barns and Granaries, with Suggestions for their Destruction. By John Curtis, F.L.S. Pp. 540, with 16 Coloured Plates, Royal 8vo. (London: John Van Voorst, 1883.)

THIS is simply a reissue of Curtis's classical work; it had long been "out of print" in booksellers' phraseology. It remains the best book on economic entomology that has appeared in this country, and has certainly served as a model for the Reports of various State entomologists on the other side of the Atlantic. No other author here has gone into the question of special injurious insects with the same care and minuteness, and it may be said that (with the exception of certain Reports issued in America) there is no similar collective work faithfully illustrated by the author's own pencil. The plates and woodcuts are in Curtis's best style, and if he had been an entomological *artist* only, his work would have remained unsurpassed.

Opinions may be divided as to the desirability of reissuing such a work "untouched," when so many years have elapsed since the publication of the chapters in the *Proceedings of the Royal Agricultural Society* that formed its basis. Much and valuable additional information has been obtained since the original articles were written, and very much alteration in nomenclature has resulted from the efforts of systematists to place this branch of entomological science on a sounder footing, but the facts remain practically unaltered, and there is the charm of a certain originality in the author's style that any radical reconstruction might have destroyed.

Nevertheless we do think it a pity that some one could not have been found with sufficient knowledge and courage to re-edit the book and bring it down to date. On the other hand, this process might have resulted in the work being no longer "Curtis's Farm Insects." Its value would be destroyed if rewritten, even by the most experienced, and we think the only practicable method of dealing with it in an absolutely new *edition* would be by means of copious annotations, not by recasting the whole.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Evolution of the Cetacea

I AM glad to be able to assure Mr. Searles Wood that I have long been familiar with the specimen called *Palæocetus sedgwicki*, preserved in the Woodwardian Museum at Cambridge, and have repeatedly examined it with much interest. It is undoubtedly Cetacean, and allied to the genus *Balænoptera*, as Mr. Seeley demonstrated, though differing in smaller size and some other characters from any existing species. As, however, the light it throws upon the evolution of the Cetacea is very small compared to the time that would have been taken up in discussing its bearings, I did not think it worth while to allude to it in a lecture of which the length was necessarily limited. It is, after all, a most unsatisfactory fragment, as its geological age is, and probably always will remain, a matter of doubt. Allowing, however, the utmost antiquity assigned to it, my argument would rather be strengthened than weakened. Mr. Searles Wood seems to have missed the fact that my chief contention was against the prevalent view that the Cetacea have been derived from the Carnivora through the Seals. Any evidence which throws back their origin in time and derives them from some more generalised type of mammals would militate against this view. No one can suppose that the Ungulata originated at the commencement of the Tertiary period, as we know that they were then already differentiated into great and distinct sections. Their primitive ancestry must therefore be looked for far back in Mesozoic times. That I thought the Cetacea existed before the Tertiary period I distinctly intimated by suggesting, as an explanation of the absence of their remains in the chalk, that they might then have been inhabitants of great inland waters, but having had so many warnings of the fallacy of negative evidence in geology, I do not yet despair of the discovery of a veritable Cretaceous whale.

W. H. FLOWER

The Java Eruption

I HAVE been greatly interested in your note on M. Renard's researches as to the composition of the volcanic material ejected during the recent eruption of Krakatoa. The ashes, as stated, are those of a magma that would have produced an andesite with rhombic pyroxene. Now such an andesite occurs at so many points, and in such immense masses, round the great Pacific "circle of fire," that one is tempted to ask if it may not specially characterise this important volcanic region. I will, with your permission, briefly refer to some published, and one or two unpublished, facts with regard to the distribution of this andesite (called hypersthene-andesite by Whitman Cross and Iddings, and bronzite-andesite by F. Becke) round the Pacific circle.

In the *Neues Jahrbuch* for 1881 (*Beilage Band* 1881, 467) Dr. Oebbeke describes, under the term augite-andesite, a rock from the Sierra de Mariveles, Luzon. Owing to the kindness of the author, I have a section of this rock before me as I write, and I have little doubt that the strongly pleochroic mineral is mainly, if not entirely, a rhombic pyroxene. Augite, however, is also present.

Passing to the other side of the Atlantic, we have recent evidence to show that a rock of the same type occurs along the line of the Rocky Mountains and the Andes.

In *Bulletin No. 1 of the U.S. Geological Survey* (1883), Mr. Whitman Cross describes a hypersthene-andesite from Buffalo Peaks, Mosquito Range, Colorado.

In the *American Journal of Science* for September, 1883, Messrs. Hague and Iddings prove that the four great volcanic peaks of Mount Rainvier, Mount Hood, Mount Shasta, and Lassen's Peak, rising to heights of from 10,500 to 14,444 feet above sea-level in California, Washington Territory, and Oregon, are mainly composed of andesitic lavas and tuffs, in which hypersthene is the predominating bisilicate.

In the *Geological Magazine* for July, 1883, Mr. Waller describes a similar rock from Montserrat, and I have just analysed one for Prof. Bonney from Old Providence Island in the Caribbean Sea. Prof. Bonney also informs me that he has found the rhombic pyroxene in the andesites brought by Mr. Whymper from Pichincha and Antisina.

It must not, however, be supposed that the rock is limited either to the Pacific region or to the Tertiary and Recent periods. M. Fouque has shown that hypersthene occurs in the Santorin lava of 1866.

Niedzwiedski described a hypersthene-andesite from Steiermark in 1872. Mr. Whitman Cross and myself have recognised the rhombic pyroxene in many well known Hungarian rocks, in which it had previously been regarded as augite. Lastly, thanks to kind assistance rendered by Prof. Rosenbusch, I have been enabled to show that some Palæozoic lavas and tuffs of the Cheviot region are of essentially the same type (*Geol. Mag.*, March, June, and August, 1883). J. J. HARRIS TEALL

Diffusion of Scientific Memoirs

PROF. TAIT's admirable remarks on the moral obligation laid upon "every society whose memoirs are worthy of appearing in print" to disseminate its publications must have awakened a cordial response in the minds of many whose lot is cast in some provincial city or outlying local college. It is only too true that the volumes of the *Cambridge Philosophical Transactions* are "almost inaccessible" to many like myself, who often find themselves tantalised by the desire of consulting some of the classical masterpieces of research or analysis therein enshrined, which, therefore, are not to be consulted without a pilgrimage to Cambridge or to London. Yet I hardly understand why Prof. Tait should—save for the occasion of reviewing the happily exhumed memoirs of Prof. Stokes—have chosen the *Cambridge Transactions* as the one instance of "inaccessibility," since it is at least equally to be regretted that a memoir published in the *Transactions of the Royal Society of Edinburgh*—and there are masterpieces of research and analysis by the score irrevocably buried therein—equally necessitates a pilgrimage on the part of the provincial reader. I, for one, shall be extremely glad if Prof. Tait will act upon his own prescription—that simple, easy cure—and consider himself "bound to disseminate as widely as possible" the memoirs which he has himself consigned to those very inaccessible *Transactions*. I doubt, indeed, if even Prof. Tait has realised the difficulty besetting a would-be reader of original memoirs and researches, who is compelled to journey from one shore of England to the other in order to consult the *Edinburgh Transactions*, the *Cambridge Transactions*, the *Comptes Rendus*, the volumes of *Poggendorff's Annalen*, or those of the *Annales de Chémie et de Physique*, or the memoirs of any one of the five great Academies of the European Continent. University College, Bristol, December 14

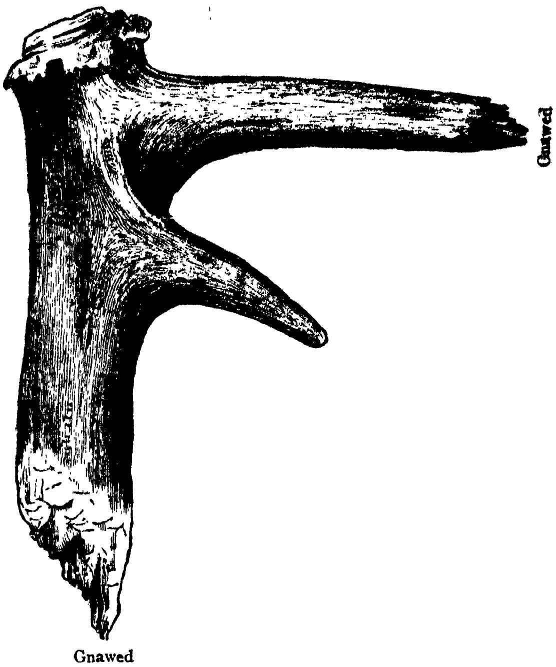
Deer and their Horns

THE question is often asked, What becomes of the horns shed every year in the deer forests? the number picked up or found hardly accounts for all those which have been shed. It is said that the deer themselves eat them. It is difficult to conceive how a deer, with its toothless upper jaw, can eat a hard bone—for such is a shed horn—but it seems probable, nevertheless, that they do so. I picked up a horn recently in the deer forest at Dunrobin which appears to show that it has been in great part eaten away; and this, I think, was the opinion of the members of the Zoological Society to whom I exhibited it last Monday. On inquiry from the head-keeper at Dunrobin, Mr. James Inglis, I find that it is the general belief that the deer do eat the shed horns, whilst the appearance of the specimen here referred to, confirms the popular belief. The marks on it are such as would be made by the broad incisors of the lower jaw, and the appearance generally suggests that the horn has been gnawed and mumbled by the cutting teeth of the lower and the toothless gums of the upper jaw. It would appear, therefore, I think, that deer do eat some at least of the shed horns, and this is rendered the more probable by the fact, according to Mr. Inglis, that there are no foxes or other animals in this particular forest to account for the mischief. J. FAYRER

December 8



Red deer's horn, eaten (by other deer?), picked up in deer forest, Sutherland, 1883. A young stag's horn.

"I BEG leave to inform you that I am unable to say from personal knowledge whether it is the stags or hinds that eat the shed horns in the forest. I have never seen either eating horns, but I have no doubt they do so, probably both stags and hinds.

"I have never known dogs to eat deer-horns, and we have no foxes in our forest, and very rarely any dogs are to be seen in it; 'even although they should eat them,' the number of pieces we find all the year round, nearly all partially eaten, leaves no room to doubt that no other animal could have eaten them. I think they commonly eat them after they have been lying exposed to the weather for some time; the horns are then softer from exposure.

"In every case that I have seen, they commence at the top or point of the horn, and eat down towards the root or burr; the latter part is often left uneaten. As soon as I can collect a few specimens I will send them to you.

"We often find horns entire without any marks of teeth on them, but those are mostly not long shed. I have also got horns that had apparently lain for years without any marks on them. But of course no one would expect all the shed horns to be eaten.

"I am sorry that I cannot give you more information, and I am also sorry that as yet I have not been able to collect more information than I know myself, but when I have any fresh evidence I will let you know. "JAMES INGLIS

Sprengel on the Fertilisation of Flowers

IN NATURE, vol. xxix. p. 29, is a letter from Prof. Hagen of Cambridge, Mass., calling attention to the fact that Sprengel's treatise on the structure and fertilisation of flowers was not unappreciated in his own day. Now it so happened that only a week or two before reading this I took up by chance the "Introduction to Physiological and Systematical Botany," by Sir James Edward Smith, the American edition, dated 1814. On p. 208 the author says:—

"Sprengel has ingeniously demonstrated, in some hundreds of instances, how the corolla serves as an attraction to insects, indicating by various marks, sometimes perhaps by its scent, where they may find honey, and accommodating them with a convenient resting-place or shelter while they extract it. This elegant and ingenious theory receives confirmation from almost every flower we examine. Proud man is disposed to think that

'Full many a flower is born to blush unseen,'

because he has not deigned to explore it; but we find that even the beauties of the most sequestered wilderness are not made in vain. They have myriads of admirers, attracted by their charms and rewarded with their treasures, which very treasures would be useless as the gold of the miser to the plant itself, were they not thus the means of bringing insects about it."

It seems to me that this is a pretty decided indorsement of Sprengel's views. W. WHITMAN BAILEY

Brown University, Providence, Rhode Island, U.S.A., December 4

Salt Rain and Dew

I SENT Mr. H. N. Draper's letter (NATURE, vol. xxix. p. 77) to my father-in law, Dr. Petzholdt, of Dorpat University, who has made a special study of South Russia, Caucasus, Russian Turkestan, &c., and his reply is that it is a fact long known to chemists that the aqueous vapour in the atmosphere due to the evaporation of sea and salt-lake waters invariably contains chloride of sodium, which is precipitated to the ground by rain and dew. Dr. Petzholdt is not aware, however, that the phenomenon is more striking on the coasts of the Caspian and Aral than in other localities. In the *Annalen der Chemie und Physik*, vol. xxxv. p. 329, Liebig writes: "All the rain water which fell in Giessen (Hesse) during two years, in seventy-seven rainfalls, contained salt." F. GILLMAN

Quintana 26 (Barrio Arguelles), Madrid, December 6

Lunar Rainbow

ABOUT 6.20 this evening I was fortunate enough to observe a fine lunar rainbow. Previous to its appearance there was a halo caused by a band of cirro-strati, which gradually developed into a crescent-shaped rainbow, which, after disappearing for a minute or two, again was observed, only circular, finally fading away as the clouds dispersed about 6.40. C. H. ROMANES

Beckenham, Kent, December 11

AT 1.30 on the morning of the 12th inst., during the progress of the storm, I looked out of the window in a north-easterly direction and observed a beautiful lunar rainbow. The arc at first was complete, and faint traces of prismatic colours, especially on the outside, were noticeable. A portion in the middle having for a moment disappeared, the complete arc again again became visible, but with only a whitish colour. M. F. DUNLOP

Greenwich, December 15

PROFESSOR NILSSON

THE oldest naturalist in the world, as respects both age and the priority of his writings, has now left it. S. Nilsson of Lund, in Sweden, was born in 1787, and therefore was nearly a centenarian at the time of his death. His earliest publication was in 1812, being a paper on the various methods of classifying the Mammalia; and in every subsequent year he enriched the scientific literature of his own and other countries. The *Annals and Magazine of Natural History* and the Reports of the British Association for the Advancement of Science, for instance, contained several articles from his experienced pen. He especially devoted himself to the fauna of Scandinavia, and became the pioneer of that host of naturalists who have so ably distinguished themselves by similar researches and publications. He was a zoologist, palæontologist, anthropologist, ethnologist, and antiquary. *Nihil tetigit quod non ornavit.*

His works consisted chiefly of scattered papers; but in 1822 he published his "Historia Molluscorum Sueciæ Terrestrium et Fluviatilium," which has still a standard reputation. As it did not include the marine or Baltic Mollusca, the gap was twenty-four years afterwards more than filled up by the eminent Prof. Lovén; and that department of the Scandinavian fauna has now, through the continual labours of the late Prof. Sars and his no less eminent son, Dr. Danielssen, Mr. Herman Friele, the Fraulein Esmark, Dr. Westerlund, the late Mr. Malm and his son, Prof. Steenstrup, the late Dr. Mörch, Dr. Berg, Dr. Collin, and many other conchologists, received as great a degree of attention as has been bestowed on any region of the earth's surface and its circumjacent seas.

The subject of this memoir was, at the last-mentioned date (1822), Regius Professor in the Academy of Lund, and the Director of the Museum of Natural History there. One of his former pupils, Prof. Otto Torell, is well known to all naturalists by his exploration of Spitzbergen, and his present position as the Director of the Geological Survey of India.

We ought to be thankful in recollecting that other veterans of science are still among us, viz. Professors Owen and Milne-Edwards at the age of eighty-three, and Dr. Isaac Lea, in his ninety-third year. The study of natural history is evidently conducive to longevity.

J. GWYN JEFFREYS

SEMITICO-OCEANIC LINGUISTIC AFFINITIES

TO the *Transactions of the Royal Society of Victoria* for May, 1883, the Rev. D. Macdonald contributes a paper, in which he endeavours to establish the identity of the Oceanic and Semitic languages. This is announced as an important discovery both ethnologically and from the theological standpoint. It clears up, we are told, "the hitherto impenetrable mystery surrounding the origin of the Oceanians," because "the Semitic language could only have been carried into Oceania by Semites from the Semitic mainland." It also disposes of the new-fangled "evolution theory," which draws support "from the existence of savages and the supposition that they are descended from 'hairy quadrupeds,' . . . for it shows, as to one of the greatest bodies of savages, that they are descended from the most renowned and civilised people of antiquity." Certainly these are weighty conclusions, which, if established, would fully justify the further inference that "this discovery is more important on the whole than that of the Assyrian or Euphratean inscriptions deciphered of late with such marvellous ingenuity."

By "Oceanic" the writer understands all the languages except the Australian current in the Indo-Pacific insular world. These he evidently regards as constituting a single linguistic family, the Malayo-Polynesian, "comprising the Malagasy, Malayan, Polynesian, and Melanesian, better called the Papuan." His philology has thus not got beyond the days of Forster and Marsden, or the earlier writings of Prof. Whitney, all of whom are appealed to in support of this now exploded theory. The readers of NATURE need scarcely be reminded that from the Malayo-Polynesian must henceforth be detached all the strictly Papuan and Melanesian tongues, as constituting a fundamentally distinct order of speech, itself doubtless embracing many stock languages. Hence the same reasoning process that establishes the identity of Semitic and Oceanic would also establish the identity of Semitic with any other stock languages wherever spoken. The process thus proves too much, that is, proves nothing.

Although Semitic is here compared generally with the whole of the heterogeneous "Oceanic" group, it is remarkable that Efatese is taken as the chief point of comparison, not that this is claimed to be a typical member of the Oceanic group, but merely because it happens to be the dialect with which the writer is most familiar. Now in Efate, a small island about the centre of the New Hebrides, there is a good deal of linguistic confusion, strictly Polynesian (Sawaiori) dialects being spoken at the Polynesian settlements of Mel and Fil, while Melanesian idioms prevail elsewhere. But from the examples adduced, and especially from such agglutinating forms as *mitángu*, *mitáma*, *mitána* = my, your, his, eye (*máta* = eye), it is obvious that the Efatese in question is not an Oceanic (Malayo-Polynesian) dialect at all, but a strictly Melanesian tongue affected by Oceanic influences. The language on which the author mainly relies is consequently useless as a point of comparison between the Semitic and Malayo-Polynesian families.

The actual relation between these two families is again stated to be "that of an ancient to a modern language, as Latin to French, Saxon to English. This implies that we shall find the Oceanic, as compared with the Semitic, characterised by phonetic and grammatical decay, &c." Doubtless there is in Oceanic, as in all linguistic groups, abundant evidence of decay. But, as compared with the Semitic, it must be regarded not as a modern, but as an almost infantile, form of speech. Semitic stands in some respects on a level with, if not even on a higher footing than, Aryan itself, as regards its grammatical evolution, whereas in Malayo-Polynesian the verb is not yet clearly differen-iated from the noun. Thus even in Samoan most of the o-called verbs are merely nouns modified by detached elational particles, and, like the adjectives, forming re-uplicate plurals. Compare *nofo* = to sit, pl. *nonofo*, with *tele* = great, pl. *tetele*. This instance alone will atisfy the ordinary linguistic student of the prodigious ulf that separates the Oceanic from the Semitic with its ighly complicated system of verbal conjugation.

And how does the writer propose to bridge over this gulf? Mainly by a string of words taken without method rom any given Oceanic language, and compared with any member of the Semitic group to which it may happen o bear some faint resemblance in sound if not in sense. No attempt is of course made to establish some general preliminary system of "lautverschiebung," without which ll such comparisons are absolutely destitute of any scien-ific value. They resolve themselves mainly into ono-atopœic forms, the common property of all articulate peech, or into some of those numerous etymological riosities which can always be found by the diligent eker, but which are such terrible pitfalls for the unwary.

Most of the Hebrew terms themselves are moreover ken either in secondary and later forms, or else in econdary and later meanings, forms and meanings which e consequently useless for the purpose of comparison etween the *organic* Semitic and Oceanic languages. hus the Efate *mitaku* = to fear, is compared with the ebrew *dag*. But this *dag*, or rather *dāag* (דָּאַג, Jer. xvii.), is a comparatively modern form of an older *dāab* אַב)), which primarily means *to melt*, and which neither in sense nor sound shows any further resemblance with he Melanesian *mitaku*. This is only one instance from mong many. The further back these supposed paral-elisms are traced, the more divergent become the lines, ntil at last they fade away into parabolic curves, and ave the gulf between these linguistic systems more im-assable than ever.

Mr. Macdonald does not expressly mention the "lost ribes." But it is on these flimsy grounds that, in a ightly incoherent concluding sentence, he claims to have ediscovered in the South Seas a lost Semitic people, their language full-orbed and in all its living vigour"!

A. H. KEANE

AMERICAN WHEAT[1]

THIS is a pamphlet issued by the Chemical Division of the Department of Agriculture, U.S., and is urther specified as *Bulletin* No. 1. It may be described as an elaborate monograph upon the composition of American wheat, and the subject is handled with great thoroughness, although the value of the result obtained falls considerably short of being startling. It is a specimen of painstaking analytical work which may form the basis for generalisations of value in the hands of able agriculturists and statisticians.

The variation in the composition of the wheat grain itself as affected by climate is rendered evident, and a comparison is instituted between the composition of European, American, Egyptian, and Australian wheats. The author in the first place produces elaborate tables of analysis, showing the composition of numerous varieties of wheat. Secondly, he considers the composition of the typical or average wheat of each of the American States. Lastly, he compares American wheats with those produced in other quarters of the globe. Among this mass of analyses it is difficult to arrive at conclusions, and there is some danger of falling into error. Mr. Clifford Richardson finds that American wheats are drier than European wheats in the proportion of 10·27 to 14 per cent. of moisture. The percentage of dry matter is consequently much higher, and the grain is proportionately more valuable. The carbohydrates average 72 per cent. instead of 68 per cent. as in the case of English wheat for example. The amount of fibre is also less in American wheats. The ash constituents are most abundant in wheat from newly cultivated tracts, and on old worn out lands both the ash constituents and nitrogen are considered to have diminished.

American wheat is, however, deficient in albuminoids to a degree which appears to disconcert Mr. Richardson more than we think it need. In American wheat we evidently have a small grain, specially free from fibre (bran), peculiarly dry, very rich in carbohydrates and oil, but deficient in albuminoids. European wheats sometimes contain 19·5 per cent. of albuminoids, and ordinarily 13 per cent. American wheats contain upon an average 11·95 per cent. of albuminoids, but in Oregon and on the Pacific coasts only 8·6 per cent. Mr. Richardson seems to overrate the importance of this fact. He appears to be in doubt as to the true importance of the albuminoids when he says, "The albuminoids are regarded, *and probably rightly*, as the most valuable part of the grain." He might, however, have been led by his investigations to doubt how far a high percentage of albuminoids is the best indication of quality in wheat. First, Australian and Egyptian wheats are both somewhat deficient in albuminoids, and are yet known to be remarkably fine. He also notices that while Oregon and Californian wheats contain comparatively low amounts of albuminoids, the grains are large and handsome. He further points out that the proportion of albuminoids in spring wheats is higher than in winter wheats, although he fails to notice that all wheat-growers know that winter wheat is better than spring wheat. Having concluded that American wheat is at fault in this particular, he endeavours to explain why such is the case with a view to remedying the defect. So far from being a fault, the richness of American wheats in starch, and the comparatively smaller proportion of glutin, appears to us as indicative of its high quality. "Tail" corn contains more glutin than "head" corn, and badly matured grains are usually rich in this important constituent. A little consideration as to the constitution of a grain of wheat will show that the glutin is not the best criterion of value. The outside layers of the grain contain the glutin, and then honeycomb cells inclose the starchy interior. This outer portion of the kernel is the first to ripen while growth still continues along the axis and in the centre. The fully matured grain, in fact, becomes like a well-packed trunk, thoroughly stuffed out, and this with starch grains. If we are correct in this view of the maturing of the grain, the percentage of glutin must diminish in proportion as starch is deposited, and increases in relative weight. We are disposed to think that the carbohydrates, and not the albuminoids, must be taken as the true criterion of quality in wheats, and that, judged by this test, the Americans have no need to fear that their wheats are inferior to those of Europe.

---

[1] "An Investigation of the Composition of American Wheat and Corn." y Clifford Richardson, Assistant Chemist. (Washington Printing Office, 83.)

The author finds a difficulty (p. 33) in accounting for the small proportion of water in American wheats. Any agriculturist would have been able to tell him that well-developed, thoroughly matured, and well-harvested wheat always contains a less proportion of moisture than wheat in an opposite condition. It is due partly to simple drying, but also to the fact that good wheat is thoroughly filled up with starch cells (carbohydrates), and that there are no fissures left for moisture or air to lurk in. Well-fed meat contains less water than badly-fed meat for the same reason, viz. the thorough filling up of the internal spaces with fat cells. A little attention to the structure of the wheat grain would have enhanced the value of Mr. Richardson's monograph.

The fact that unripened and badly matured wheat is often rich in glutin is well known to chemists, and we are disposed to think that the richness of European wheat in this constituent is partly due to the fact that it is often defectively matured.

After treating exhaustively upon the composition of American wheat, the author proceeds to treat of flour and bread, and lastly of other cereals and maize. The pamphlet certainly repays the trouble of perusal, and indicates the vast pains which is now being taken by the United States Government in order to bring scientific knowledge to bear upon its most important industry. The wheat production of each State is watched with minute care, and the quality of the produce is subjected to analysis. It is gratifying to notice that Canadian wheat is in all respects equal to that grown in the United States.

JOHN WRIGHTSON

College of Agriculture, Downton, Salisbury

THE REMARKABLE SUNSETS

SINCE our last number appeared the view that the recent wonderful sunrise and sunset phenomena have really been due to the terrible eruption of Krakatoa in August last has been confirmed in the most definite manner. Material brought down by rain in Holland and snow in Spain has on microscopic examination proved to be identical with actual products of the eruption brought from Krakatoa in the ordinary manner.

The following letter to the *Times* from Mr. Joseph McPherson, an eminent geologist now in Madrid, must be read in connection with the letter from Holland given below:—"Desirous of obtaining positive proof of the brilliant theory put forth in your columns relative to the cause of the remarkable appearances at sunrise and sunset which have for many days excited public attention, I have this day analysed some fresh-fallen snow with the following results, namely, that I have found crystals of hypersthene, pyroxine, magnetic iron, and volcanic glass, all of which have been found in the analysis lately made at Paris of the volcanic ashes from the eruption of Java."

This being so, every fact connected with the displays instead of losing really gains an additional interest, and now that we know we are in presence of the work of the upper currents each date becomes of great importance.

The extraordinary fact now comes out that before even the lower currents had time to carry the volcanic products to a region so near the eruption as India an upper current from the east had taken them in a straight line *viâ* the Seychelles, Cape Coast Castle, Trinidad, and Panama to Honolulu, in fact very nearly back again to the Straits of Sunda! The 5th of September is now fixed from two sources as the date of the first appearance of the strange phenomena at Honolulu.

Mr. Bishop thus writes to the *Saturday Press* (published at Honolulu, September 22), which has been forwarded to us by the courtesy of the Hawaiian Consul at Glasgow:—

"I first noticed these peculiar appearances on Wednesday the 5th inst. at 7 p.m., so long after sunset that ordinarily no trace of colour remains on the western sky. The sky, from south-west to west, was then covered with a lurid red and dull yellow glow, much resembling that produced by a distant conflagration. This extended to an altitude of 15° or 20°. I continued to distinguish the light till 7.25."

He then proceeds:—

"I would note three peculiarities of the phenomenon, distinguishing it from ordinary sunset reflections, and unlike anything I remember to have observed before: (1) It appears to be a reflection from no cloud or stratum of vapour whatever. (2) The peculiar lurid glow as of a distant conflagration, totally unlike our common sunsets. (3) The very late hour to which the light was observable —long past the usual hour of total cessation of twilight. To this may be added (4) that the centre of brilliancy was more or less to the south of west."

Mr. Bishop at once ascribed the phenomena to Krakatoa dust, and suggested more vivid appearances along the line Honolulu, Ladrones, Manila, Sunda. Of course he knew nothing of the line Panama, Trinidad, Cape Coast Castle, Seychelles, Sunda.

In a subsequent communication Mr. Bishop tells us that the after-glow remained brilliant for some time, being very brilliant on September 30. The haze stratum was visible as a continuous sheet at a height far above that of the highest cirrus, a slight wavy ripple being noticeable in its structure, always perfectly transparent and invisible except under certain conditions. A conspicuous circle of 15° to 20° radius was observed during several days, "a misty, rippled surface of haze, with faint crimson hue, which at the edges of the circle gave a purplish tint against the blue sky."

He states that Capt. Penhallow, of the *Hope*, observed these phenomena in lat. 24° N., 140° 29′ W., on September 18.

The following notes as to the eruption itself we take from the *Straits Times*, as dates and times are mentioned:—

"In the afternoon of Sunday, August 26, a rumbling sound was generally heard at Batavia, coming from the west, like that of far distant thunder varied by strong detonations, the concussion from which shook and rattled doors and windows on all sides . . . . especially when on the night between August 26 and 27 these phenomena steadily became more violent until 1 a.m., when a detonation was experienced which brought about such a concussion that the gaslights here were all as it were extinguished at the same moment. Many persons, anxious for their wives and families and for life and limb, hence forbore to sleep and awaited the morning in great excitement. Morning broke, but the sun, instead of shining with that clear brightness which characterises the morning hours in the East, concealed itself, and the whole sky seemed overcast. At 7 a.m. on that day, August 27, the first shower of ashes was noticed here, from which it was inferred that whatever might be the volcano at work in the neighbourhood, the outburst must assuredly be appalling when ashes in showers could be noticed even in distant Batavia. The ash showers fell heavier, and before the hour of midday had struck the whole of Batavia was enveloped in thick darkness. From the lack of sunlight the temperature fell several degrees. People shivered with cold, their discomfort being heightened by anxiety, especially when lamplight had to be used at midday. Like a mountain a great sea wave came rushing on along the whole coast of West Java, forced its way into the rivers, thus causing them instantly to rise several yards and overflow th banks. Indescribable was the confusion into which prahus, steamboats, and tambangans were thrown in the lower city, and no pen can depict the confusion in old Batavia, resulting in especially the natives and Chinese seeking safety by a general flight. To give some idea of the tidal waves which agitated the sea and rivers, we need only say that at Tanjang Priok, in particular, the water rose ten feet within a few minutes, that it not only wholly overflowed a portion of Lower Batavia quite suddenly, but also bore fully laden prahus of twenty-five lasts and even more capacity ashore like straws. This phenomenon was repeated at 2 p.m., but not so violently. However great was the force exerted by this heavy flow, there came a moment, after it had raged its utmost, when the water in masses of immense height suddenly ebbing away vanished, and left the river beds and sea bottom a while dry. Meanwhile, the thick, heavy, and oppressive atmosphere, charged with sulphurous fumes, began to clear up somewhat in spite of the cold. It became lighter, and by the increasing light people beheld a sight seldom certainly witnessed here in the course of centuries. The streets, or rather the roads, the trees, and the houses, were covered with a wholly white layer of ashes, and presented in the land of the sun a genuine Dutch winter scene. In the meantime, when, later in the day the distant detonations had ceased and rumbles had become fainter, no one had yet the least idea of the havoc wrought by this strange natural phenomenon. By that time Anjer had been flooded and devastated by tidal waves; with few exceptions its inhabitants had been drowned in a moment of time, and on its site in the course of that disastrous Monday nothing but an extensive muddy morass could be seen." EDITOR

We have received the following communications:—

EARLY in the morning, on December 13, between four and five o'clock, a violent tempest from the north-west arose. The temperature in the course of the morning was rather low, viz. 4° C., and, especially between six and seven, the wind was accompanied by showers of rain, intermingled with hail. This rain was of a peculiar nature, every drop, after having dried up, leaving behind a slight sediment of grayish coloured substance. This was most distinctly to be seen on the panes of windows turned towards the west or the north-west; the spots with which these panes were dotted did not leave the least doubt about their having been caused by the fallen rain.

The streamlets of rain, having evaporated, left on the whole surface of the windows the said grayish matter behind, so that there can be no doubt but the rain itself had conveyed from the upper air the above dust.

The magnificent "cloud-glow" which, on several previous evenings, had also been observed hereabouts, and which has been attributed by meteorologists—with good right, no doubt—to the volcanic ashes due to the catastrophe of Java, made us suppose that the substance observed by us on the windows could not but be of the same origin. We took it for granted that whirlwinds, when the storm set in, had brought the dust down to the lower regions of the atmosphere, where it mingled with the falling rain. Consequently we proceeded to examine microscopically the sediment, in order to compare it with original ash from Krakatoa, which had been sent to the Agricultural Laboratory at Wageningen to have its value as plant-food ascertained. The result of this examination was that both the sediment and the volcanic ash contained (1) small, transparent, glassy particles, (2) brownish, half ransparent, somewhat filamentous, little staves, and (3) et black, sharp-edged, small grains resembling augite. The average size of the particles observed in the sediment was of course much smaller than that of the constituents of the ash. These observations fortify us in our supposition, expressed above, that the ashes of Krakatoa have come down in Holland.

Wageningen, December 14 M. W. BEYERINCK
J. VAN DAM

WITH every spare cranny in NATURE filled with volcanic dust, and the whole discussion in far abler hands than mine, I should be loth to trouble you, were there not one point in connection with the recent optical phenomena which has, as far as I know, escaped observation, and which may possibly be worthy of consideration. I allude to the connection between the sky-glows and the phenomenon commonly known as "*Rayons de Crépuscule*."

To the latter phenomenon I have incidentally had my attention much drawn, having been for many years engaged in a set of cloud observations for a special purpose. This appearance has already been described, and to some extent discussed, in the pages of NATURE and elsewhere. Several other phenomena, some of them occurring while the sun is above the horizon, seem to have been confounded under the same name. That of which I now write consists of red rays converging to a point near the horizon opposite to the sun's position, usually at between fifteen and fifty minutes after the sun has set or before it has risen. On rare occasions I have seen these belts in the evening extending past the zenith so as to converge towards the position of the sun beneath the western horizon. The interspaces of these rays (which, as has long ago been explained by Mr. Lockyer, are the shadows of hills or clouds beyond the visible horizon) are often of a complementary blue-green. The colour of the rays is similar to that reflected at an earlier hour in the evening, or at a later in the morning, from the most elevated cirri. This phenomenon seems to be in itself almost entirely independent of any weather conditions, occurring under utterly diverse states of the atmosphere. It possesses one remarkable characteristic. It is far more common in Europe in the month of November than at any other period of the year, although the prevalent state of our November skies is scarcely such as to favour its visibility. To this characteristic I called the attention of some scientific friends several years ago, amongst whom I may mention the name of Robert H. Scott, F.R.S. I have thought that the "*Rayons de Crépuscule*" were somewhat more common in the years when the November meteors were most abundant. But if this prove to be the rule the exceptions are numerous. There are long periods during which there are no "*Rayons de Crépuscule*," or in which if they occur our view of them is entirely obstructed. I have always supposed that the fall of meteoric dust determines the condensation and congelation of the vapour which exists in those strata from which these red rays are reflected, just as London smoke determines the formation of spherules of fog. The solar rays are thus reflected from ice spiculæ suspended in the atmosphere, rather than, as I understand Prof. Brücke to imply, from the atmosphere itself. Are there any reasons for doubting the possibility of the existence of much water vapour at a far greater elevation than this stratum? This would ordinarily remain in the vapour state, being above the ordinary range of the *pulverised* meteorites.

Now the same orange-red glow in the east, from ten to twenty minutes after sunset, by which I have usually been able to predict the appearance of "*Rayons de Crépuscule*," has been almost constantly visible at that hour throughout the present period. Further, this has been followed slightly on one, and vividly on two, of those evenings when the succeeding glow was most remarkable, by the "*Rayons de Crépuscule*" themselves. And the rays of red light emerging on several occasions from the effulgent glow in the west appear to me closely to resemble western continuations of very elevated "*Rayons de Crépuscule*."

Ecce iterum. Here we come back to Krakatoa. Granting the distance to which the vapour and dust were ejected from the bowels of Krakatoa to have been so great that the more rapidly rotating surface of the earth brought Panama under this vapour and dust in the space of less than a week, we have a gigantic pepper-box capable of condensing and congealing vapour which had long remained undisturbed in its serene heights. We do not need to call in the known currents of the atmosphere to explain the dispersion Poleward and therefore eastward of the volcanic matter, gravitation alone accounting for the transmission of the particles down the inclined isobaric planes.

To my theory of ice spiculæ it has been objected that these ought to produce halos. So, whenever the recent phenomena have been most strikingly developed, they have done. Yesterday was the third occasion during this period when, from 2.15 to 2.50 p.m. the sun was surrounded by a remarkable halo, the sky at the time being totally devoid (in the neighbourhood of the halo) of any visible upper clouds whatsoever. Cumuli passing the halo appeared green. The halo was followed by a splendid glow in the evening, and again this morning.

December 15 W. CLEMENT LEY

IF you are not yet suffering from a plethora of letters on this subject, I should like to add a few remarks to those which have been already made.

On Thursday, December 6, I witnessed one of these gorgeous sunsets in company with a friend, from the top of Rusthall Common, near Tunbridge Wells. Like Mr. Rollo Russell, I noticed that the peculiar *lasting* glow came from a lofty stratum of pale, fibrous, nearly transparent cirriform haze, which was almost invisible as the sun set, but afterwards came gradually into view, at first white in colour, and then gradually changing to orange, pink, and finally red, the change to pink occurring at 4.25 and to red at 4.45.

We also observed a strange reactionary effect produced by this glow, viz., that long after the red tints had faded from the ordinary cirrus in the western sky and from some snow-shower cumuli in the east, they were both relighted by the glow which had meanwhile increased in the west.

On Friday, this reflection *on to low clouds all over the sky* from the undoubtedly lofty stratum in the west was more noticeable, and it at once struck me that persons who had not observed the entire process of the extinction of the real reflection of the sun by these clouds, and their subsequent reillumination by reflection from the *upper* glow (as Miss Ley terms it), might erroneously be led to attribute this secondary illumination to their reflection of direct sunlight. On this ground alone, I should be rather inclined to accept with a little hesitation the observation on which Prof. Helmholtz bases his calculation, viz., that the clouds which were illuminated by the sun were 45° *above the horizon two hours after sunset.*

Nothing that I saw on either Thursday or Friday at all favoured such a fact. On the contrary, there was some positive evidence in favour of the reflecting medium being situated at a much more moderate altitude. In the first place, judging by an eye often engaged of late in taking vertical angles with a theodolite, I should say that on both days (when the sky was very clear and the stratum which emitted the glow was unusually well defined) the maximum height of the glow-stratum was not more than from 10° to 12° above the horizon.

Moreover the interval between when the ordinary cirrus ceased to glow and this upper stratum began to glow corresponded very much more with a height of from ten to thirteen miles than with such an enormous height as forty miles.

Miss Ley has, I believe, already calculated the height of the stratum to be thirteen miles, and I think this height is far more probable than one of forty miles. Besides, can we imagine either vapour, or volcanic dust, or a mixture of both, to be capable of remaining in suspension in air of such tenuity as must exist at such an altitude? Moreover, I think it must be admitted that whatever be the cause, whether meteoric dust, or impalpable pumice carried over by the upper anti-trade currents from the Java eruption, the reflection arises from a definite stratum and not merely from an atmosphere filled throughout with such dust. Possibly, as Mr. Edmund Clark suggests, the dust may act as a nucleus for the condensation of any vapour that may exist at such a high level, and it is possible that just as we find certain definite positions at which condensation occurs, and therefore clouds float, at lower altitudes, so there may be some particular height at which condensation is determined in these upper regions, thus accounting for the definiteness of the reflection and the presence of the cirrus haze to which it apparently belongs.

Thus, Dr. Vettin of Berlin has recently shown that the clouds have a marked tendency to float at certain defined levels, which can only be supposed to result from the action of certain physical causes regarding whose nature we are at present entirely ignorant.

The name of the cloud and the corresponding elevation in feet are as follows :—

Name of stratum	Height in feet
Lower cloud	1,600
Cloud	3,800
Cloudlets	7,200
Under cirrus	12,800
Upper cirrus	23,000

Now we see that these heights increase very nearly in a geometrical ratio, with 2 as the common factor, so that we might anticipate a tendency for cloud to be formed (assuming that the empirical relation held good) at an elevation of about 46,000 feet, or a height of nearly nine miles. It would be at least interesting to find that the average height of the reflecting layer in these recent sunsets lay at about this elevation.

Another circumstance which favours the notion that the dust would be carried from the tropics, and float above, and not below, this level is that, while at all lower elevations the polar currents predominate, it is just about this same level that the equatorial or southerly air-currents begin to exceed those which have a northerly component in strength and frequency. Thus, according to Vettin, the following figures represent the relative volumes (?) [1] of air carried by the equatorial and polar currents at different altitudes over Berlin :—

Equatorial	Polar	Height in feet
305	226	From 41,000 feet up to the extreme limits of the atmosphere.
253	228	41,000
206	222	23,000
164	212	12,800
108	131	7,200
92	118	3,800
83	158	1,600

This table, I think, makes it easier to understand how the dust should have been transported over to extra-tropical regions from the neighbourhood of Java, and why it should appear only in the *very high strata.*

E. DOUGLAS ARCHIBALD

GILBERT WHITE of Selborne, in one of his letters (lxv., to the Hon. Daines Barrington), describes the "amazing and portentous phenomena" observed in the summer of 1783. "The sun at noon looked as blank as a clouded moon, and shed a rust-coloured ferruginous light on the ground, particularly lurid and blood-coloured at rising and setting. The country people began to look with a superstitious awe at the red lowering aspect of the sun; and indeed there was reason for the most enlightened person to be apprehensive, for all the while Calabria and part of Sicily were torn and convulsed with earthquakes, and about that juncture a volcano sprang out of the sea off the coast of Norway."

---

[1] I have not the copy of the *Zeitschrift* by me just now, and am only quoting from memory. I cannot therefore be sure whether it is volumes or frequencies. For the purpose in hand either would do equally well.

Those who are familiar with the letters and poems of Cowper will remember his references to the same phenomena in that year, as in "The Task," Book ii.—

> "Fires from beneath, and meteors from above
> Portentous, unexampled, unexplained,
> Have kindled beacons in the skies; and th' old
> And crazy earth has had her shaking fits
> More frequent, and foregone her usual rest."

Mrs. Somerville, in her "Physical Geography," traced the origin of these atmospheric phenomena to the great eruption of Skaptar, one of the volcanoes in Iceland, which broke out May 8, and continued till August, sending forth clouds of mingled dust and vapour, which spread over the whole of northern Europe. Mr. Henderson, in his work on Iceland, and Dr. Daubeny in his work on volcanoes, also describe this eruption, and the enormous quantities of volcanic dust sent by it into the atmosphere.

Mr. Norman Lockyer ascribes the recent abnormal sunrise and sunset phenomena to the clouds of volcanic dust from the great eruption of Krakatoa on September 2. The different effect caused by a tropical eruption and one in northern regions would be such as Gilbert White observed, and what we have lately witnessed. In the eruption of 1783 the stratum of dust and vapour must have been at a low level compared with that of 1883. We know in a general way the course of the circulation of the atmosphere, as we do that of the ocean: the flow of currents from the Poles to replace the ascending volume of air in the equatorial zone, which gradually diffuses itself in the upper regions of the atmosphere. But of the direction and velocity of these lofty strata we know little in detail; just as we have variations and unexplained diversions even of oceanic currents, but in the atmosphere to far greater extent. From Humboldt and Arago we have been taught to believe that the pumice and vapour clouds from volcanoes are raised to enormous altitudes, and the dispersion of these may be too irregular to admit of calculating the exact time after a tropical eruption when atmospherical phenomena would appear in particular localities. The fact remains that abnormal atmospheric effects have resulted from the presence in upper regions of the air of pumice dust in unusual quantity.

In some regions of the earth these phenomena have been frequently observed, as on the coasts of Peru, where we would expect a large amount of volcanic dust to be present. In Ellis's "Voyage to the Sandwich Islands," he describes just such appearances as we have been recently seeing. "Towards evening and in early morning I have seen clouds of every hue in different parts of the heavens, and such as I had never seen before: for instance, rich and perfect green, amber, carmine; while the hemisphere round the rising and setting sun has been one blaze of glory." Similar sunlight effects are described by Bishop Heber in his narrative. "Besides tints of crimson, flame-colour, &c., there were large tracts of translucent green in the immediate neighbourhood of the sinking sun, and for some time after sunset; with hues such I have never seen before, except in a prism, and surpassing every effect of paint or glass or gem." These effects were such as aqueous vapour alone could not have produced, and were doubtless due to foreign matter in the upper regions of the atmosphere.

In the meteorological observations of Luke Howard there are several records of similar abnormal sunlight effects when the sky was "deep blood-red after sunset, with hues passing through crimson and a gradation of lighter reds and orange and flame colour." Whether these appearances can be connected with particular volcanic disturbances or not, they seem to have been due to the presence of foreign matter in the upper strata of the air; and there are rarely periods when some volcanic region is not in active eruption.

On more than one evening in December the metallic-green colour of the moon attracted general notice. This was not due to the laws of complementary colour, for it remained when not a vestige of red or crimson could affect the vision. Mr. Edward Whymper states that the peculiar hue recalled to him the same appearance as witnessed by him in South America when the atmosphere was charged with volcanic dust.

JAMES MACAULAY

IN 1880, when travelling in Southern Algeria, I was talking with some colonists about a simoom, when a Frenchman present exclaimed "C'est la première fois que j'ai vu le soleil bleu." Upon interrogation I was assured by the whole company that the sun, seen through the fine dust of a Sahara wind, had a decidedly blue colour. I do not know whether this is always the case when a storm is blowing from the desert; but the fact, even if not a regular one, throws some light upon the East-Indian green sun. It confirms evidently the opinion that the green colour and the remarkable weakness of the sun's light, as observed in India, were due to volcanic dust from Krakatoa. An eruption like that of August must throw up into the highest layers of the atmosphere dust not only in enormous quantities but also of extraordinary fineness. And I see no difficulty in assuming that this dust, transported by air currents over Africa and Europe, was the cause of the "remarkable sunsets," the more so, as the latter phenomenon is evidently a wandering one. At Constantinople the first remarkable sunset was observed on November 20 (splendid), and subsequently we saw the same glow of the heavens in the morning and evening of the first five days of December, though partially masked by clouds. Afterwards the observation was rendered impossible by bad weather.

Constantinople, December 12 DR. BUDDE

I HAVE read with great interest the accounts of the extraordinary sunsets we have had lately. I have watched all the effects most carefully for the last fortnight, and it may be of some interest to you to hear my account. The first time I noticed anything very odd was on the evening of the 24th. I was then calling on a friend who lives on this lake, and it was dark enough to have candles, when on looking up at his studio window I saw three or four masses of cumuli piled up against each other, and all of unusual, or rather I should say unnatural, colour. I said to my friend, "Well, I never saw such a sky or clouds, it is exactly like an old master picture, like a rich Titian sky." . . . I said this because what *ought* to have been blue sky was quite a rich green, and some of the clouds rich amber, others red brick colour, and others a yellow green. There was a high wind; these clouds were in the north, or nearly opposite the sunset, and very near. I was startled, because I knew some of the colours to be unnatural, especially at that time of day (4.30); it was not a green or an amber I had ever seen, and I have watched the sky very carefully for many years. Then, about a week ago, I saw the same effect again, and on looking round towards the sunset my eye caught the crescent moon; it was of a *pale blue green*. Two evenings before this, I was startled on looking up from my book (and some time after candles had been brought in) to see quite a red glare behind the "Old Man"; as it was almost night, I thought it was some large fire, but on going out I saw that it was merely a glare from the sunset; and more to the east near the horizon there were lurid masses of red cloud very far off showing through bars of nearer gray cloud. I thought of running into Ruskin's study and telling him to look, and went as far as his door, but then deemed it better not, as the effect was of so lurid and awful a nature, I thought it might put him off his work! My next scene was one morning; finding the room very dark, I suddenly discovered the maid had shut the shutters; I got up to open them, and to my astonishment saw Coniston *Old Man all red*, but with no shadows! I was all the more astonished because it was still much too dark for any light on the "Old Man" at all! and I can assure you it really looked *alarming*. I have of course often seen the mountain red and orange, but never before sunrise. I concluded that this glare was caused by some very bright reflection from the rising sun on the sky above, and bright enough to make the mountains all red. I watched this more or less until nine o'clock, when at last the usual shadows appeared, the mountain getting I suppose some real sunlight. Then my last effects have been two extraordinary after-glows a few evenings ago. It seemed to me that about half an hour before sunset the sun began to shine through some extraordinary vapour capable of being illuminated *very much* more than the ordinary atmosphere, so much so that we had faint *cast* shadows from it on our lawn; there was no sign of the sun or even where he was, as this vapour was so *equally* illuminated. It lasted long; and when candles had been in some time, there was still a band of *intense rose* colour on the western horizon.

ARTHUR SEVERN

Brantwood, Coniston, Lancashire, December 9

THIS atmospheric phenomenon still continues morning and evening to excite admiration. Its effects, however, on the colour of the sky disappear at an earlier hour than has hitherto been the case; on the morning of Wednesday, the 5th inst., the southern heavens were resplendent with richest and most brilliant colours, to attempt the description of which would be somewhat puzzling. It seems as if of late the grandest displays occur before sunrise. The afternoon effects were remarkable less for richness of coloration than for the lustre of the light which arose in the west after sunset and for the predominance over the whole sky of opalescent white colours. The reflection of the light on church towers and buildings brought out the architecture in strong and startling relief. There was, however, at 4.15 p.m. a colour display, and on this occasion the moon for a short time was again changed to a hue of emerald green. On the 6th, before sunrise, the phenomenon reappeared in a mantle of lurid red colour. The display passed through the usual changes of colour and disappeared when the sun rose. In the afternoon the glow at 4 p.m. reappeared, followed by the usual brilliant radiance; the colours were, however, sea-greens, opaline whites, and bright grays till 4.30 p.m., when a blood-red colour overspread the western sky. The glow faded sooner than usual. The morning of the 7th though splendid was less grand in character than the display of the previous morning. At 4 p.m. a rosy hue suffused a few light clouds that rested on the sky. At 4.15 pearly whites and mauves and grays prevailed. Just at this time an irregularly shaped vaporous mass of an exquisite tint of lake formed in the west 45° above the horizon, and gradually spread to a point near the horizon. At 4.30 the usual orange-coloured arc appeared in the west, and for a few moments the light emitted was almost dazzling. The display was somewhat evanescent. On the 8th, before sunrise, the sky was enriched with various hues of red, carmine, green, and yellow. At 3 p.m. there was a detached cloud canopy coloured with a deep rose, but changing to an orange hue; 5 p.m. dense cloud canopy with red radiance visible through the clouds. On the 9th a dense cloud canopy shut out observation. At 4 p.m. a bright yellow glare coloured the horizon of the western sky. This was followed by the orange-coloured radiance, but the display was fugitive. The morning and afternoon of the 10th were unfavourable for observation owing to a dense cloud canopy, but a yellow-coloured light in the sky was perceptible. On the 11th the sky before sunrise was brilliant with colours pink, blood-red, yellow, and green. At 8 a.m. for a few moments the sun appeared of a green colour. This afternoon's effects were very beautiful. At 3 p.m. a yellow glow prevailed: this gave way to a remarkable streak of a vivid green colour extending along the horizon from north-west to south-west; above this was a vaporous mass reaching to within a few degrees of the zenith. Beyond this mass and overspreading the zenith the colour was mauve. In the eastern sky the colours were reds, mauves, and blues. This evening the moon again shone with a green light. The glowing arc of orange-coloured radiance which evening after evening shone in the western horizon seems to have ceased to be apparent here. The effects of the splendid sky coloration in causing the flame of gas lamps to appear white, or rather in fact to resemble the electric light—noticed by Mr. Sydney Hodges at Ealing—was at this place a striking feature of the displays. A destructive hurricane from the north-west set in at 11 p.m. on the 11th inst., and was of greater violence than any that has occurred here from that point for these forty years. The night was moonlight, with flying scud. In the night, between one and two o'clock a.m., during the height of the hurricane, the phenomenon of paraselene or mock moon was visible. The false disk was well defined, equalled the moon in size, but was less brilliant, and was some 4° or 5° from the true moon; prismatic halos were visible during the night. The wind blew in terrific gusts, striking houses and buildings almost with the force of a battering ram. Before sunrise on the 12th a red glare suffused the sky, and at half-past eight a.m. the sun appeared of a dark green colour, and remained of this colour for several minutes. The violence of the hurricane subsided towards four a.m. During the lulls of the storm there were on one or two occasions tremors that I could not connect with the vibration of the house from the effect of the wind, and which seemed to me to be earth tremors. In the afternoon the glow appeared in the west in the shape of a mass of a luminous yellow body some 25° above the horizon, which sank gradually below the horizon, and left a clear sky. On the morning of the 13th the only colour visible was a deep yellow, and that colour prevailed in the vicinity of the sun throughout the day. Thermometer again rose to 50°, barometer falling. In the afternoon of that day, cloud obscuration shut out observation.

December 14.—At sunrise, owing to the denseness of the prevailing cloud canopy, observation was not possible. At 10 a.m. the canopy broke up and dispersed, and, except along the eastern horizon, the sky became blue and clear. At 11 a.m. a broad, colourless stream of remarkable moving vapour or cloud haze, and rayed, nebulous cirri of a very filmy structure, issued from a point occupied by a few clouds of the stratus type on the western horizon, and travelled across the zenith eastwards. The motion of the vapour and cirri was rather fast as it swept across the sky. The quick-changing forms were most astonishing, some being of a leaf structure, some pointed rays, some curled, others horizontal bars. The forms of both haze and cirri were most fantastic. The stream continued to flow till after 2 p.m. I have never before observed anything like it. At 3.15 p.m. there was a wide-spreading green sky space about 20° in altitude on the western horizon. Above it gradually in the clear sky, a rich russet glow, with no definite outline, became developed, and continued to prevail. A 4 p.m. a pink glow coloured some clouds resting on the western sky and flushed the entire horizon. Towards 5 p.m. the russet colour gave way to a smoky yellow tint, and soon afterwards the light disappeared. Cloud-forms during the day took the most weird and fantastic forms. Imagining that the phenomenon was on the wane, I was surprised to witness a display so brilliant and imposing. On this day the thermometer rose to 54°. At 8 p.m. there was a rather broad band of green light round the disk of the moon. It seemed to me that neither the sun nor the moon during the days and nights of the 12th, 13th, 14th, and 15th gave the usual light.

December 15.—The sunrise this morning was of a most impressive character. From just before sunrise till 8 a.m. the eastern sky was flushed with blood-red colour. At 8 a.m. the sun again shone with a most beautiful green light for a few minutes. The room in which the observations were made has two windows, one facing east, the other south, and the marvellous spectacle was witnessed of a flood of crimson glare filling the east window, while through the south window poured a volume of dazzling green light. This afternoon there was a thick cloud canopy, and rain fell, but a yellow glare penetrated the clouds on the south and west. At 4 p.m. through a cloud rent could be seen the bright pink, russet green, and yellow colours of the glow. The thermometer registered 44°.

December 16.—The glare was visible this morning, but no colour other than smoky yellow was visible. Afternoon the glare very powerful, but at 3.45 pale yellow was the only colour. This, however, prevailed in the west, but extended round the whole horizon. The spoked ray feature, however, was greatly developed.

The steel coloured radiance which glowed in the western sky at 3.30 p.m. at the time of closing my letter was followed from 4 till shortly after 5 p.m. by the fiery glare which has been a marked feature of the red sky displays during their prevalence. The sky effects were much the same as on the previous afternoon, except that the nebulous matter was traversed by fan-shaped pointed rays, and its structure presented a billowy appearance.

December 17.—Glare at sunrise as on other mornings of late, the coloration less grand and brilliant. During the morning a stream of filmy cirri issuing from the point in the heavens occupied by the sun and travelling across the zenith till after midday. 3.30 p.m.—Steel coloured glare, followed at 4 p.m. by the development of the usual fiery glow in the western sky, traces of which remained till 6 p.m.

In the "Notes" in NATURE for the 6th inst. (p. 135) is a record of a fall, on the night of Nov. 17, at Storelvdal, Norway, of layers of gray and black dust. This was the day of the date of a fall of discoloured rain near Worcester. Recent accounts announce the visibility of the phenomenon in America, where its cause is ascribed to meteoric dust. Reports of falls of ashes on land and shipboard tend rather to strengthen the volcanic dust theory. According to the "Annals of Philosophy," vol. ii., the sun appeared of a blue colour in April of the year 1821 in England. It seems from other sources that there were in February of that year a violent volcanic eruption in the island of Bourbon, and in June of the previous year a destructive outbreak in Gunung Api.

Worcester, December 17 J. LL. BOZWARD

THE following observations of the remarkable "glow" that has lately been attracting such universal attention at sunrise and sunset may be of use for comparison with similar phenomena observed in other parts of the world. They relate to the phenomenon as observed at sunrise on those occasions when the atmospheric conditions and other circumstances have been favourable for obtaining good observations, though I may state that, even when cloudy, and no clear blue sky visible, the red glow has frequently made itself apparent through the clouds.

December 4.—6.40 a.m. The whole eastern sky between the east-north-east and south-west, for an altitude of 15°, was of a pale pink; at 7.15 it had increased in altitude to 45°, and near the horizon was of a deep crimson. At 7.30 it began to fade away, changing to a yellowish pink, and at 7.45 it had disappeared, excepting a slight crimson haze having an altitude of about 10°, and confined to that portion of the horizon at which the sun was about to make his appearance.

December 12.—6.30 a.m. A narrow belt of brilliant crimson clouds about 5° wide skirted the horizon between the north-east and south-south-east; at 7 it had considerably decreased in brilliancy, and reached an altitude of 15°, and at 7.30 it had become of one uniform pink colour, and now reached the great altitude of 60°. It now began gradually to fade away, changing to a yellowish pink, and rapidly decreasing in altitude until by 7.45 it had entirely disappeared, leaving a clear blue sky, which at 7.50 became tinged with the ordinary sunrise tints.

December 13.—6.50 a.m. A bright yellow glow having an altitude of 15°, appeared on the horizon, extending from the east-north-east to the south-east; at 7.20 it had increased in altitude to 60°, the upper portion being of a pink colour, giving to the blue sky immediately adjoining a sickly green tint. At 7.50 the pink glow near the zenith had disappeared, and the yellow glow near the horizon had changed to pink; it had now decreased in altitude to 10°, and extended no further than between the east and south-east points of the horizon. As the sun rose above the horizon it again changed to yellow.

December 17.—7.15 a.m. The clouds which up to this time had overcast the sky cleared away, although a very brilliant display of the "glow" was to be seen. The entire eastern sky between the east-north-east and south-south-east for an altitude of 75° was of a beautiful pink, excepting immediately on the horizon, where it was yellow. At 7.45 the glow disappeared, leaving a clear blue sky until 7.55, when the usual sunrise tints made their appearance.

From the foregoing remarks it will be seen that the "glow" in this locality has generally made its appearance 1h. 20m. before sunrise, and excepting in one instance (December 4) it has disappeared ten minutes before the sun has made his appearance above the horizon.

Dalston, E., December 18 B. J. HOPKINS

I HAVE observed the "after-glow" here (Madrid) since November 30, when it first came under my notice. The effect was particularly fine on the 2nd inst., the atmosphere being perfectly clear, and the moon (new, two and a half hours behind the sun) quite brilliant, as also the stars. At 4.24 (Madrid time) the sun went down, and we had a fine, but not unusual, golden sunset effect which lasted about fifteen minutes. At 5 the sky was gradually lit up again, say 100 miles north and south of sun point on the horizon, and some 45° of arc above, the colour varying from pink-red to crimson, less intense on high, but with a defined semicircular boundary against blue sky, which at this period assumed a *greenish* tint, as did also the moon without losing her brilliancy. But I did not observe any "streaks of Polar auroral light," mentioned in Mr. Bozward's letter; the crimson fan (shall I say?) was uniform, and maintained its intensity till six o'clock, though it gradually receded; the moon at the same time recovering her silvery appearance; and at 6.15, that is one hour and forty minutes after sunset, all was over. At 6 p.m. the barometer (4-inch height aneroid by Ladd) marked 705·50 mm. (say 27·80 inches; Madrid is 655 metres above the sea), and the thermometer (Casella, K.O., No. 9538), sheltered, 4 metres above ground, stood at 10° Cent.

On the 3rd inst. the effect was somewhat different, owing to slight haziness, coupled with delicate ripples of cirrus above, a few streaks of heavy cloud down on horizon, and slight breeze from south-west; but the whole phenomenon on the 4th inst. was the most instructive. These are my notes:—

4.34 p.m. sundown; usual sunset effect, golden; massive horizontal streaks of neutral tint cloud, from 5° to 20° above horizon, with intervals, coloured Indian red; cirrus above light crimson. 4.50, all over, clouds no longer illuminated, sky on horizon dull yellow. 5 p.m., yellow band turned *pale green; low clouds remaining quite dark* (not illuminated), upper transparent cirrus pink or light purple. *gradually* fading off into blue atmosphere, which remained *decidedly blue* although the moon and haze circle round her (= four moon diameters) were decidedly *greenish*. 5.15, purple fan receded or contracted somewhat, and more crimson in colour; green tint on horizon fainter. 5.25, upper purple tint quite gone; light down on horizon bright red like conflagration (or iron heated to redness); moon greenish; *heavy cloud streaks quite dark;* and here I will say that although I noticed in Madrid a very slight breeze from north-west, *all* clouds remained to all appearance perfectly stationary from beginning to end. 5.35, at this moment the lower clouds (say to 20° above horizon) were *reilluminated as at sunset* from beneath (Indian red), after remaining forty-five minutes in total shade. At 5 45 this new illumination began to fade, and the red glow on the horizon had risen somewhat, and was dusky. 5.50, only a few red streaks under the clouds; glow as before, apparently more intense, owing to increasing darkness. 6.0, glow dull, and low down on horizon, nearly all on the north side of the sun's setting point. 6.15, all over. Barometer 702 mm. (say 27·65 in.); thermometer 12° C.

Since December 1 the whole phenomenon, without losing intensity, has become reduced in extent, *i.e.* the fan of light (so to speak) is getting smaller, especially in the direction of its length on the horizon. Yesterday (5th) I noticed the same *reillumination* of cloud; to-day we had heavy clouds and rain at the time, and barometer 699 mm. and thermometer 6° 5 at six. F. GILLMAN

Quintana 26 (Barrio Arguelles), Madrid, Dec. 6

THERE has been a very fine "glow" this evening, with the delicate rose tint which is so unusual. I observed the bands at C and D very strongly marked, and also a faint band at about *a*, and another about half way between C and D. This is the best marked evening glow that we have had here since about the end of last week.

Dublin, December 14 J. P. O'REILLY

SIGNOR DENZA, Director of the Central Observatory at Moncalieri, writes that these sunsets were seen from November 25 to December 1, and again from December 4 to December 7, throughout the whole of Italy from the Alps to the extremity of Calabria, and everywhere with great intensity. A vast number of reports have been received at the Central Observatory, generally to the same effect. So vivid was the glow, that by many observers it was taken for an aurora borealis, the prevailing colours oscillating between red and deep orange, and afterwards passing through all the tints to the most delicate pink. During the evenings of November 28 and 29 nearly the whole sky was lit up, and the phenomenon was followed first by storms, fogs, and rain, and later on by snow. Observed with the spectroscope, the light presented nothing but the usual absorption lines of the vapour of water, but very intense. Before dawn and after sunset the zodiacal light was seen very distinctly.

Numerous letters have appeared in the *Times* on the sunsets during the past week:—

MR. G. J. SYMONS sends the following extract from the Meteorological Report from Adelaide Observatory, South Australia, for October, 1883:—"On every clear evening during this month, and the last fortnight of September, a peculiar phenomenon has been apparent in the western sky. Shortly after sunset a red glow will make its appearance, at an altitude of about 50°, being very faint at first, but as the brightness of the sky near the horizon dies away with the receding sun, the red glow will expand downwards, becoming at the same time more brilliant, until at last the whole western sky will be lit up with a beautiful light, varying in colour from a delicate pink to a most intense scarlet, and the spectacle presents a most brilliant appearance. The upper part will then gradually fade away until the colour is noticeable only 7° or 8° above the horizon, at which time the light is at about its brightest. Afterwards, a secondary glow will sometimes make its appearance at an altitude of about 50°, and gradually spread downwards until the sky is again lit up. In the secondary phenomenon the colours are generally more delicate. The whole thing will fade away about 8 p.m. This phenomenon has been noticed all over the south-eastern portion of this continent, from Port Augusta (lat. 32° S.) to Melbourne; and in India the sun has at times presented a most peculiar appearance, being green at rising, then gradually changing to a blue at noon, and inversely from noon to sunset. Various theories have been started to account for the phenomena."

COL. STUART-WORTLEY states that in 1862 he spent a year in South Italy on purpose to study the formation of clouds by the aid of photography. "During that time I spent some time at Naples while the great eruption of that year was going on, and was struck with the unusual colours of the sunsets during and after the eruptions. I still have photographs of both sunrises and sunsets indorsed with memoranda as to unusual and exceptional colours." Four years ago, while sailing in the Pacific, Col. Stuart Wortley was much struck with the fact that very frequently the whole vault of heaven was overspread with magnificent and glorious colouring, and that in the higher regions of the air colours were found that were never seen at the horizon or below a certain height. "Now, this exceptional magnificence and peculiarity of colouring only occurs in certain latitudes and in well-defined belts, and I venture to suggest that, seen in the light now thrown on the subject by Mr. Norman Lockyer and others, the constant stream of volcanic matter thrown out by the great volcanoes in the mountain ranges of South America, and possibly from elsewhere, form an almost permanent stratum of floating matter, carried in certain directions and kept in certain positions by alternating currents in the higher regions of the air, and that to this stratum of volcanic matter much of the exceptional colouring found to be associated with sunrises and sunsets in portions of the Southern Pacific Ocean is due."

MR. W. H. PREECE writes:—"I think I can add one link to Mr. Lockyer's chain of reasoning. If we assume that the mass of volcanic matter projected with such force into the atmosphere in the Straits of Sunda was highly electrified, then it must have been electrified with the same sign as that of the earth—viz. negative. Therefore, when the force of projection had exhausted itself, the cloud of matter would be subject to two other forces besides gravity—the repulsion of the electrified earth, and the self-repulsion of each particle of electrified dust. The first would determine the tenuity of the cloud, for the lighter the particles the further they would be repelled, and the heavier the particles the quicker they would descend. It is quite possible to conceive that they might be so minute and so highly electrified as to reach the utmost confines of our atmosphere, where they would remain as long as they remained electrified. The second repulsive force would cause the particles to spread out continuously in a horizontal plane until they would cover an area determined only by their quantity. When we take into consideration the movements of the atmosphere and the rotation of the earth, I see no reason to doubt that an immense cloud of highly electrified matter, projected into the atmosphere in Java, could spread itself in the higher regions of the atmosphere over an area equal to that of Europe. That this is not fanciful is proved by the behaviour of smoke. I have often watched when at sea, on a still, calm day, the black smoke of some passing steamer rise to some determined height, and then gradually spread itself at an equal and constant distance from the sea like a great flat pall. I have also seen on land the smoke from some manufacturing shaft blown gently by the wind follow the curves of the land, remaining always at the same distance from the ground, but gradually spreading outwards in every direction. I have also seen two lines of smoke refuse to coalesce, but repelling each other exactly as they ought if they were similarly electrified. That smoke is, therefore, negatively electrified I firmly believe, though I have never tested it. Now, that this wonderful atmospheric disturbance was accompanied by extraordinary electrical disturbance was shown, not only by Capt. Watson's observations near the spot, but by Prof. Smith's records at Madras, and hence it requires no great stretch of the imagination to conceive electricity playing a great part in the recent gorgeous display of atmospheric effects."

IN reference to Mr. Preece's letter, Mr. Crookes writes:—"In a paper read before the Royal Society in 1879 I showed that at a rarefaction of the millionth of an atmosphere two pieces of electrified gold leaf repelled one another at a considerable angle for thirteen months without loss of charge. Therefore at a rarefaction of a millionth (corresponding to a height above the earth's surface of about sixty-two miles) air is a perfect nonconductor of statical electricity, without interfering with the mutual repulsion of similarly electrified particles. When we bear in mind that the specific gravity of gold is five or six times that of the rock whose disruption formed the dust in question, and that the size of the individual particles of dust is certainly many thousand times smaller than my gold leaves, there is every reason to believe that electrified dust, once projected fifty or sixty miles above the earth's surface, might remain there for many years."

BISHOP BROMBY, writing to the *Times*, says that in a letter from a member of his family at Hobart, Tasmania, the writer speaks admiringly of "the loveliest after-glow which was spread over the sky on the other side of the water where the sun had set." This was written on October 12 by one who was ignorant that similar phenomena had been observed in other parts of the world.

ANOTHER correspondent of the *Times* states that in a letter dated "Duem, September 24, 1883," Hicks Pasha wrote:—"By the way, have you in England noticed a large black spot on the sun? To-day, when it rose, it was of a pale green colour, and we saw through our glasses an immense black spot on the lower half of it. What does this portend? I feel sure there must be some notice of it in the papers in England."

SHERIFF RAMPINI of Lerwick, Shetland, writes that the sunsets have been observed in these northern islands.

MR. G. F. BURDER of Clifton sends the following extract from a letter from a passenger travelling from San Francisco to Sydney, three days after leaving Honolulu. The writer says:—"On Wednesday, September 5, we witnessed a most curious phenomenon. The sun set perfectly blue, and next morning it rose a flaming ball of blue. The blue light was reflected in our cabins."

ON November 30, at 4 p.m., another remarkable sunset was observed in Stockholm. A correspondent states that the western sky became covered with an intense purple after-glow, having the appearance of an enormous distant conflagration, which nearly reached the zenith, and lasted for an hour, even after it was dark, and the stars were visible. On the morning of December 1 a similar intense light was observed at sunrise. The colour was, however, then more yellow. The phenomena have also been observed in the north of Sweden, in Gothenburg, in Christiania, and in Copenhagen.

THE KRAKATOA AIR-WAVE

ON Thursday last Mr. R. H. Scott communicated a paper to the Royal Society giving a map and tabular statements concerning certain barometric disturbances observed towards the end of August last.

The obvious correspondence of the forms and times of occurrence of the barometric disturbances, described in Mr. Scott's paper, at once suggested to General Strachey that they were due to a common origin, and the great volcanic eruption at Krakatoa in the Straits of Sunda appeared to supply a probable efficient cause. General Strachey therefore took up the question from this point of view, and at the same meeting communicated a paper, of which the following is an abstract:—

"Any shock of sufficient violence might be expected to produce an atmospheric wave, advancing from the place where it was caused in a circular form round the globe, at first expanding until it had got half round the earth, and then again contracting till it was again concentrated at the antipodes, from which again it would be thrown back, and so pass backwards and forwards till it was obliterated. It might have been expected that such a wave would travel with the velocity of sound, being probably of the same nature as that which causes sound, though the vibrations had not the peculiar character that affects our organs of hearing. It has, however, been suggested to me that the wave may rather have had the character of a solitary wave produced in a liquid, the velocity of which in the air would not materially differ from that of sound.[1]

"A rough examination of the facts at first made known by the observations recorded in Great Britain indicated that there was *primâ facie* strong evidence in support of this view, and that the phenomena would be approximately explained by the passage round the earth of a series of waves travelling at the rate of about 700 miles an hour in opposite directions from the place where the volcanic eruption occurred. The records since procured from other places, and the more careful examination of the facts, have quite confirmed this conclusion.

"Although we may expect to obtain additional data from other parts of the globe, which will make the investigation of this somewhat remarkable phenomenon more complete, yet those we now have are sufficient to justify an attempt being made to bring the more important facts before the Royal Society without further delay.

"The following table shows the stations from which the records have been received of which use has been made in this discussion, with certain particulars of their geographical position, and of their distances measured on great circles, from Krakatoa, the place of eruption:—

---

[1] The log of a surveying ship at the north of Borneo, since received, shows that the explosions were heard there on the morning of August 27, at a distance of 1200 miles from the volcano; and it has been also stated that these sounds were heard in Ceylon, at a distance of about 2000 miles.—R.S.

"As the earlier disturbances, on August 27 and 28, extend over several hours, it became necessary to fix on certain sufficiently well defined points in the curves representing the barometric pressure, from which to measure the epochs of the passage of successive disturbances. The *first* and *second* of the series are, in almost all the curves, well defined and generally similar in form, commencing with a distinct rise, which is again followed by a distinct fall, the fall being shorter than the rise. These features are followed by a less definite rise succeeded by a shallow fall, after which there is again a rise, which gradually passes into the more regular trace.

"The *third* and *fourth* of the disturbances can be traced in all the curves, but they no longer exhibit the same characters, and are usually nothing more than a sudden sharply defined rise, though in front of some of these there is a more or less distinct trace of a hollow.

"The *fifth* and *sixth* of the series become less distinct and are lost at several stations, being usually rises; while a *seventh* faint disturbance, as a shallow hollow, can be traced in a few of the curves, after which nothing can be distinguished.

"By a comparison of the time intervals between the first and third, the third and fifth, and the fifth and seventh disturbances, and assuming (which the facts seem to justify) that the velocity of the wave has remained unchanged in its passage from east to west, it would appear that the first well-defined rise in the first of the series corresponds to the rises which are prominent in those succeeding it. And the same conclusion has been drawn from an examination of the second and fourth compared with the fourth and sixth of the series.

"Adopting these conclusions, the times of the successive passages of the initial rise have been measured from the curves, suitable allowance having been made where the rise was difficult to trace, or, as sometimes happened, a hollow appeared corresponding in position with the hollows in the earlier form of the disturbances. There is, of course, some doubt attaching to these measurements, but their general consistency seems to indicate that they may be accepted as fairly representing the facts under discussion.

"The following table gives the results of these estimates of the times at which the successive waves passed the several stations, reckoned from midnight of Aug. 26, in Greenwich mean time:—

Place	Times of passage of wave.						
	I.	II.	III.	IV.	V.	VI.	VII.

St. Petersburg ...	11 15	28 40	48 30	63 50	84 40		

"From these figures are deduced the intervals between the successive passages of the waves from east to west, and from west to east, respectively, or of the times of travelling round the earth, which are shown in the next table, for all stations excepting Toronto.

"From the results thus obtained it would follow that the wave travelled round the earth from east to west in 36h. 57m., being at the rate of ·1026 hour for one degree of a great circle of the earth, and from west to east in 35h. 17m., being at the rate of ·098 hour for one degree. From the velocities thus determined the probable time of the origin of the wave has been calculated from the known distance of each place from Krakatoa, the time occupied in the passage of the wave from Krakatoa to the place of observation, and the observed time of the passage of the waves.

Intervals occupied in travelling round the earth.

Mean excluding Toronto	37 4	36 54	36 48	36 57	35 24	35 9	35 17

"The mean value thus obtained from the waves moving from east to west for the time of the origin of the disturbance at Krakatoa is 2·52h. Greenwich mean time, or 9·53h. local time, that is 9h. 32m. a.m. of August 27.[1]

"In like manner the waves travelling from west to east gave results which were exhibited in another table.

"The mean value of the time of the origin of the disturbance obtained from the waves moving from west to east is therefore 2·20h. Greenwich mean time, or 9·21h. local time, that is, 9h. 13m. local time.

"The mean between the two values obtained from the waves travelling against the earth's motion of revolution, and those travelling with it is 2h. 24m. Greenwich mean time, or 9h. 24m. local time, August 27.

"The velocity of the waves in miles will be for those which travel from east to west 674 miles per hour, and for those passing from west to east 706 miles per hour. The velocity of sound is for a temperature of 50° F. 757 miles an hour, and for 80° F. 781 miles an hour. With a temperature as low as zero F. the velocity will only be reduced to 723 miles an hour, which is still considerably in excess of the greater of the observed velocities. The excess of the velocity of the waves which travelled in the same direction as the earth's motion of revolution, that is, from west to east, over that of those which passed in the opposite direction, is about 32 miles an hour, which might be accounted for by the circumstance that the winds along the paths of the waves would, on the whole, be from the west, which would cause an increase in the velocity of the one set, and a diminution in that of the other, so that the observed difference of 32 miles would correspond to an average westerly wind of 16 miles an hour, which is not improbable.

"It should be observed that the path of the wave which passed Toronto approached very near to the North and South Poles, and that the velocity in both directions appeared to be somewhat less than in the waves which passed over Central Europe. The wave which passed northwards over Asia travelled at the rate of about 660 miles an hour, or about 15 miles an hour slower than the wave which passed over Great Britain from east to west. This reduction of velocity seems to be within the limits of what might be due to the low temperature of the regions.

"The wave travelling from east to west having been perceptible on the barometer traces at several of the stations until about 122 hours after its origin, and its velocity having been 674 miles an hour, it had travelled before its extinction more than 82,200 miles, and had passed 3¼ times round the entire circuit of the earth.

"It is further worthy of notice that during August 30 and 31 and September 1, a very severe cyclonic storm was crossing the North Atlantic, and that the wave coming from the westward early on the 31st, No. VI. of the series, must have passed on in front of the cyclone, and that its next transit would have carried it into the very centre of the cyclone near the British Isles on the afternoon of September 1. This perhaps accounts for no trace of it being found, though the wave coming from the eastward on the morning of that day, just before the cyclone had arrived, No. VII., was discernible.

---

* At these stations the fifth transit cannot be traced.

[1] It has not been thought necessary to give *in extenso* the table showing the separate values deduced from the several observations, but they differ from the mean by in no case more than a few minutes.

"There is no definite statement, so far as I am informed at present, of the true time of any particularly severe shock or explosion at Krakatoa excepting that which is contained in the letter of Mr. Watson (published in NATURE, December 6, 1883), whose ship was within a few miles of the volcano on the morning of August 27. He refers to an unusually severe explosion as having occurred at 11h. 15m. a.m. local time, which is nearly 45 minutes later than the time, 9h. 32m., arrived at in the foregoing discussion. The point of the disturbance (as indicated by the barograms) which has been taken as the front of the wave is the highest point of the first abrupt rise of the trace, and is perhaps, on an average, not far from one hour after the first signs of disturbance, the increase of pressure having been very rapid during the interval, but broken into two or three steps or oscillations. During the following half hour there is usually a large decrease of pressure, succeeded by another abrupt rise lasting about half an hour. Then follow a fall of about an hour, then a rise of an hour and a half, and then a fall of an hour and a quarter. The whole length of the disturbance on the time scale is between five and six hours, corresponding to an actual distance of between 3500 miles and 4000 miles. The length of the first main wave of the disturbance is about one hour on the time scale, or about 700 miles in length over the earth's surface.

"In the present position of our knowledge of the facts, it can only be surmised that the shock of 11h. 15m. a.m. of August 27, observed by Mr. Watson, corresponds to the second main feature of the disturbance. That the wave which forms the first feature would have originated at 11h. 15m. a.m. is apparently inconsistent with the observed velocities, which it has been shown are remarkably consistent, and indicate without much doubt an origin at 9h. 32m. a.m.

"The barometric disturbance at Mauritius noted by Dr. Meldrum is said to have begun soon after 11 a.m. local time. The distance from the volcano to Mauritius being about 3450 miles, the wave at the rate of 674 miles per hour would have reached the island in 5h. 7m. Taking the great shock at 2h. 32m. Greenwich mean time, as before reckoned, the wave would reach Mauritius at 7h. 39m. Greenwich mean time, or adding the allowance for difference of longitude, 3h. 50m., the local time would be 11h. 29m., which agrees satisfactorily with the facts as recorded.

"In conclusion, it may be noticed that the sea-waves produced by this volcanic disturbance, assuming the time of its occurrence to have been 2h. 32m. Greenwich mean time on August 27, were propagated with an approximate velocity of 480 miles an hour to Mauritius, of 430 miles an hour to Port Elizabeth near the Cape of Good Hope, and 420 miles to Galle, and a somewhat slower rate to Aden. The details of the occurrence of these waves on the coasts of India will shortly be laid before the Society by Major Baird, who has informed me that the velocity of the wave between Galle and Aden was 378 miles an hour, and the lengths of the great waves from 287 to 630 miles."

"P.S.—December 15. Since the above was read before the Royal Society a copy of the barometric trace from New York has been received, which shows disturbances very similar to those recorded at Toronto, and at times which are quite in accordance with the general conclusions stated in the paper."

NOTES

IN connection with the resignation of Prof. Sylvester of his Chair in the Johns Hopkins University, we find that it was resolved at a meeting of the trustees held October 1, "That as this resignation is doubtless the result of mature reflection on the part of Prof. Sylvester, it is hereby accepted, but that in doing so the Board of Trustees cordially extend to him its hearty thanks for the invaluable services which he has rendered to the University, and also its profound sense of the great ability, the conscientious fidelity, and untiring energy with which he has discharged the arduous duties of his Chair, thereby elevating the science of mathematics to its proper plane, not only in this institution but in this country." It was also resolved "That Prof. Sylvester be appointed Professor Emeritus in the Johns Hopkins University."

IT may be remembered that at the recent Geodetic Congress the French delegates opposed the adoption of Greenwich as the universal meridian, though M. Faye was in favour of the adoption of Greenwich time. At the meeting of the Paris Academy on December 3, M. Faye, whilst supporting the proposal that the universal time should be that of Greenwich, stipulates for the civil hour instead of the astronomical hour, and for the counting of longitudes from 0h. to 12h. positive towards the east and negative towards the west, instead of from 0h. to 24h. reckoned towards the east, but leaving it to astronomers and navigators to employ at discretion for the universal time that according to civil or astronomical reckoning, as may seem best.

A MEETING was held in Sheffield last week for the purpose of carrying out, in connection with Firth College, a proposed technical department having reference to the trade of the district. Among those who spoke were Mr. Mundella and Dr. Sorby, and we need not say that all agreed as to the desirability of establishing such a department, and the necessity of educating our captains, as well as our privates, of industry, in the principles of their crafts. For that, Mr. Mundella insisted, is the true technical education. He gave the experience of a friend who has just been visiting the United States, and inspected the means for technical education existing there; the distinct conclusion was "that there is more skill and intelligence in American industrial pursuits than there is in our English industrial pursuits." It is much that we know our weakness and are taking means to remedy it. No doubt the Firth College will soon have a well equipped technical department.

THE Lecture Arrangements at the Royal Institution before Easter, 1884, are as follows:—Prof. Dewar, six lectures (adapted to a juvenile auditory) on Alchemy (in relation to modern science), commencing on Thursday next (December 27); Mr. R. S. Poole, two lectures on the Interest and Usefulness of the Study of Coins and Medals; Mr. A. Geikie, five lectures on the Origin of the Scenery of the British Isles; Prof. J. G. McKendrick, five lectures on Animal Heat: its Origin, Distribution, and Regulation; Prof. Ernst Pauer, six lectures on the History and Development of the Music for the Pianoforte, and its Predecessors the Clavecin, Harpsichord, &c.; Prof. Tyndall, six lectures on the Older Electricity, its Phenomena and Investigators; Prof. Henry Morley, six lectures on Life and Literature under Charles I.; and Capt. Abney, six lectures on Photographic Action, considered as the Work of Radiation. The Friday Evening Meetings begin on January 18, Prof. Tyndall on Rainbows. The discourses on the other evenings will probably be as follows:—Rev. T. G. Bonney, the Building of the Alps; Prof. Max Müller, Râjah Râmmohun Roy; Mr. G. J. Romanes, the Darwinian Theory of Instinct; Prof. Thorpe, the Chemical Work of Wöhler; Sir Frederick Bramwell, London (below bridge) North and South Communication; Prof. Hughes, Theory of Magnetism (illustrated by experiments); Mr. C. V. Boys, Bicycles and Tricycles in Theory and Practice; Mr. J. N. Langley, the Physiological Aspect of Mesmerism; Mr. Walter Besant, the Art of Fiction; Prof. O. Reynolds, the Two Manners of Motion of Water (shown by experiments).

EVERY one must wish well to the scheme for an Institute for East London, to the meeting in connection with which last Friday at the Mansion House the President of the Royal Society gave the benefit of his experience as an East End doctor forty years ago. The demand for such commodities as the Institute would furnish is strong enough; eminent men of science who have lectured in Whitechapel on their special subjects tell us that the largest obtainable place of meeting in the district is invariably crowded.

A MEETING and *conversazione* will be held under the auspices of the National Association of Science and Art Teachers, in the Manchester Technical School and Mechanics' Institution on Saturday, December 22. Prof. Roscoe, F.R.S., will take the chair. It is expected that a large number of science and art teachers will be present, including visitors and delegates from the Liverpool, Birmingham, and Newcastle-upon-Tyne branches of the Association. It has been arranged on this occasion to bring together for exhibition a collection of apparatus, models, text-books, diagrams, and appliances of a new and interesting nature bearing upon the study of science and art. We have no doubt the meeting will be a successful one. The Association is calculated to be of great service to science teachers, and deserves encouragement. Prof. Huxley is president, and the secretary is Mr. W. E. Crowther, Technical School, Manchester.

AT the last meeting of Superintendents of National Education at Washington, Prof. Bickmore described the lectures on natural history which he now gives every Saturday to school teachers, and the first history of these lectures. The authorities of the Natural History Museum wrote to the Board of Education in New York suggesting that a select few of their teachers should come to hear an informal address upon the objects there exhibited. Sets of these lectures were attended first by those few, then by fifty, then by over one hundred teachers. They are now given to a full hall every Saturday. No continued systematic series of illustrations could be met with, so a photographer was employed to take transparencies of specimens and copies of various illustrations bearing upon the subject to be exhibited by the oxy-hydrogen light. Another lantern is also used to throw light upon the written lists and diagrams or upon objects which are arranged in pigeon-holes, upon each one of which exactly the lecturer can throw the light as it is wanted.

AFTER some interesting reflections upon the wonderful strides in population revealed by the last United States census, Dr. Harris pointed out to the same meeting how partial would be the value of any special technical education that might be given to a whole school. He urged that mechanical inventions were every day throwing out of work "hands" that had acquired manual dexterity. Education of the brain to directive intelligence is the great want. The large development of invention is set down to the study of natural science and of the phenomena of physical processes. On the other hand, the relish, by many students at least, for manual instruction leads the authorities at Boston to report that "manual training is so great a relief to the iteration of school work that it is a positive benefit rather than a detriment to the course in the other studies."

WE learn from Trondhjem that the starling has been seen for the last two winters in the north of the Trondhjem Amt, sitting on the roofs of houses at Christmas time, notwithstanding the cold, which was considerable for the season. In the present year some of the birds are again to be seen after their usual period of migration.

Naturen reports that Prof. Heiberg of Christiania has demonstrated the presence in the air passages and pulmonary substance of hares of a form of strongylus, both barren and charged with ova, which would appear to be the cause of an otherwise unexplained mortality among these animals in the autumn of last year in the district of Eidsvold in Norway.

SEVERAL Russian writers have of late been drawing attention to the fact that the Japanese seas harbour various species of fish which are poisonous. Dr. Sawtscherks even suggests that ships going to these waters ought to be provided with descriptions and representations of these suspected fish, of which twelve varieties would appear to belong to Tetrodon, *T. inermis*, the Japanese "Kanatuka," being reported as especially venomous. According to Dr. Guldrew, one Japanese fish, known as Fuku, is so poisonous that death follows almost instantaneously after eating only a moderate-sized bit of the flesh. The Japanese are forbidden by law to eat this fish, but it is nevertheless not unfrequently the cause of death among the lower classes, who believe it to be possessed of certain marvellous properties, on account of which they risk the danger of being poisoned.

IT is evident that we have much yet to learn respecting insects which habitually go through their early stages in *sea water*. In the current number of the *American Naturalist* (December, 1883) is a account by A. W. Pearson of the larva of the Dipterous family *Stratiomyiidæ* that was found by him beneath *Zostera* on the beach near the mouth of the Merrimac River. With a few exceptions all marine insects are either Coleopterous or Dipterous, and it is the latter order especially that shows itself the most diversified in point of larval adaptation to extraordinary conditions.

M. TILLO publishes in the last number of the *Isvestia* of the Russian Geographical Society the results of very accurate measurements he has made of the lengths of the rivers of Russia in Europe. The measurements have been made on the ten-versts-to-an-inch map of Russia, and present great differences with those which were published by General Strelbitsky in his work, "Superficie de l'Europe;" these last have been made on a map of a much smaller scale (sixty versts to an inch), and contain several errors. The figures of M. Tillo are, on the average, by 26 per cent. greater than those of M. Strelbitsky, showing thus the error which may ensue from measurements made on smaller maps; several rivers, as the Kama, Dnieper, Dniester, and Oka, are, in M. Strelbitsky's measurements, respectively by 200, 285, 300, and 315 versts too short; whilst the ten versts' map has given to M. Tillo a length of the Dnieper only by one-twentieth shorter than the three-versts-to-an-inch map. The chief rivers of Russia appear now with the following lengths: Volga, 2108 miles (the verst being taken equal to 0·663 miles), Ural, 1480 miles; Dnieper, 1329; Don, 1124; Kama, 1117; Petchora, 1024; and Oka, 915 miles.

IN the same periodical, M. Woeikof points out that the tea tree and the bamboo could be advantageously cultivated in Russian Transcaucasia. The most northern point where he has seen the tea tree in Japan is Akita, close by the western shore of Niphon, under 39° 45′ N. lat.; and he has been told that it is grown even at the frontier of Amovori, under the fortieth degree of latitude. The average temperature at Akita would be, according to meteorological observations at Niigata and Hakodade, about 11°·5 Cels. for the year, zero in January, 23°·5 in July, and 24°·5 in August. The tea tree grows very well also in the valleys at Ponevara, under 38° N. lat., 900 feet above the sea-level, where the average yearly temperature is no more than 12°, and that of January no more than 0°, whilst every year there falls a deep snow. As to the bamboo tree, it is cultivated under 39° 10′, 500 feet above the sea-level, on the western slope; and under 38° 35′, 400 to 450 feet above the sea-level, on the eastern slope. In the western parts of Transcaucasia, between Batoum and Tuapse, the average yearly temperature varies from 13° to 15°, and that of January is between 4°·5 to 6°·5. Both are thus higher than those of Japan. The summer is, perhaps, a little colder, but this difference would hardly exercise any influence. Even in the interior of the country, up to the Great Caucasus ridge, and east to that of Meskhi, the average temperatures at places up to 1000 feet above the sea-level would allow the culture of the tea tree. As to the rains, they are quite sufficient in Western Transcausia, whilst in the eastern parts of the country irrigation would be necessary.

L'Astronomie states in its last number, in reference to a recent note in NATURE, that Admiral Mouchez has drawn up a memorial praying for the removal of the Paris Observatory from its present position, but that he has not yet presented it to the Council of the Observatory, but will do so at an early period. It is not the first time that the idea has been started. The proposal was made in 1868, and a Commission appointed to report on the matter. The scheme was objected to strongly by Leverrier, and finally rejected after a very sharp discussion.

THE Swedish frigate *Vanadis* has just started on a cruise round the world. King Oscar's second son participates in the cruise, as well as Dr. Hjalman Stolpe, who has been commissioned by the Government to collect materials for the nucleus of a National Ethnographical Museum in Stockholm. The frigate, whose mission is chiefly scientific, will call at many places of interest, as, for instance, the Straits of Magellan, the Marquesas and Sandwich Islands, the remarkable Malden Island, &c. A Swedish merchant, M. Fürstenberg of Gothenburg, has contributed 600*l*. for the purchase of objects of scientific value.

M. BOURDALOU, having published in 1864, in his work, "Nivellement Général de la France," that the average level of the Mediterranean is by 0·72 metres lower than that of the Atlantic, this result was received with some distrust by geodesists. General Tillo points out now, in the last issue of the Russian *Izvestia*, that this conclusion is fully supported by the results of the most accurate levellings made in Germany, Austria, Switzerland, and Spain, which have been published this year. It appears from a careful comparison of the mareographs at Santander and Alicante by General Ibanez, that the difference of levels at these two places reaches 0·66 metre, and the differences of level at Marseilles and Amsterdam appear to be 0·80 metre when compared through Alsace and Switzerland; the *Comptes Rendus de la Commission Permanente de l'Association Géodésique Internationale* arrive at 0·757 metre from the comparison with the Prussian levellings, whilst the fifth volume of the "Nivellements der Trigonometrischen Abtheilung der Landesaufnahme" gives 0·809 *viâ* Alsace, and 0·832 *viâ* Switzerland. The difference of levels at Trieste and Amsterdam, measured *viâ* Silesia and Bavaria, appears to be 0·59 metre. Each of these four results (0·72, 0·66, 0·80, and 0·59), having a probable error of 0·1 metre, their accordance is quite satisfactory, and we may admit thus that the average level of the Mediterranean is in fact lower by 0·7 metre than that of the Atlantic.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. J. L. Waldon; a Night Heron (*Nycticorax griseus*), European, presented by Mr. N. H. Fenner; two Barbary Turtle Doves (*Turtur risorius*) from North Africa, presented by Miss Stewart; four Ring-hals Snakes (*Sepedon hæmachetes*), a Hoary Snake (*Coronella cana*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Black-faced Kangaroo (*Macropus melanops* ♂) from Australia, a Broad-nosed Lemur (*Hapalemur simus* ♂) from Madagascar, an Exanthematic Monitor (*Varanus exanthematicus*) from West Africa, purchased.

OUR ASTRONOMICAL COLUMN

THE MASS OF SATURN.—Prof. Asaph Hall has communicated to the Royal Astronomical Society a note upon the mass of Saturn deduced from observations of the outer satellite *Japetus*, made with the 26-inch refractor at the Naval Observatory, Washington, in 1875, 1876, and 1877. The mean distance of the satellite from its primary, reduced to the mean distance of the latter (9·53885), was found to be 515″·522 from 128 observations. For the periodic time of *Japetus* Prof. Hall compared his own observations with one by Sir W. Herschel on Sept. 20, 1789, and with Sir John Herschel's observations made at the Cape of Good Hope in 1837. The resulting sidereal revolution is 79·3310152 days. Hence the mass of Saturn in units of the sun's mass is $\frac{1}{3482·2}$. Bessel, from heliometric measures of the great satellite *Titan* obtained a value of $\frac{1}{3501·6}$, which has been since used in nearly all calculations where the mass of this planet enters; Jacob, from observations of *Titan* made at Madras in 1856–58, inferred a mass of $\frac{1}{3487·2}$, which it will be seen closely approaches that given by Prof. Hall. The value deduced by Leverrier from the theory of Uranus is $\frac{1}{3529·56}$, and therefore is the smallest of all.

CLOSE DOUBLE-STARS.—M. Perrotin has published in the *Astronomische Nachrichten* further measures of double-stars made at the Observatory of Montgros, Nice, amongst which are some of the close binaries. In July last he thought 72 Ophiuchi (rather a problematical object) might be elongated in the direction 110°, but in the following month it appeared single under good conditions of atmosphere. Of the closer stars we find—

		Position	Distance
		°	″

24	0	3	37	17	59·9	9·8678	9·8894
26	0	11	57	20	48·2		
28	0	19	44	−23	25·1	9·8966	9·8901

The intensity of light is at a maximum in the middle of January. The comet will be nearest to the earth on January 9, distance 0·634, or rather less than two-thirds of the earth's mean distance from the sun. At its last appearance in 1812 it did not approach the earth within about 1·35.

TEMPEL'S COMET, 1867 II.—M. Raoul Gautier of Geneva is engaged upon a revision of the orbit of this comet, which, it may be remembered, experienced great perturbations from a near approach to the planet Jupiter during the revolution 1867–73. It may probably arrive at perihelion again about May, 1885. If there should still be unpublished observations of this comet, it would be desirable to communicate them at once to M. Gautier, that they may be brought to bear upon his investigation.

DE MORGAN'S FIVE-FIGURE LOGARITHMS.—There is a report that the five-figure tables of logarithms of numbers and trigonometrical functions published "under the superintendence of the Society for the Diffusion of Useful Knowledge," but which are usually known as De Morgan's Tables, are out of print, and that there is no present intention of a further issue. If this be the fact, it is much to be regretted: they are by far the most convenient five-figure tables that we possess, on the score of size and legibility, and have been widely utilised in astronomical calculations. Lalande's Tables, the stereotype edition of Firmin Didot, are good, and the same may be said of Gauss's, where i is of advantage to have two degrees on one opening; but w nevertheless unhesitatingly give the preference to "De Morgan."

PROBABLE NATURE OF THE INTERNAL SYMMETRY OF CRYSTALS

SOME studies pursued by the writer as to the nature of molecules have led him to believe that in the atom-groupings which modern chemistry reveals to us the several atoms occupy distinct portions of space and do not lose their individuality. The object of the present paper is to show how far this conclusion is in harmony with, and indeed to some extent explains, the symmetrical forms of crystals, and the argument may therefore in some sort be considered an extension of the argument for a condition of internal symmetry derived from the phenomena of cleavage.

If we are to suppose that crystals are built up of minute masses of different elements symmetrically disposed, it is natural to inquire in the first place what very symmetrical arrangements of points or particles in space are possible.

It would appear that there are but *five*, which will now be described.

If a number of equal cubes are built into a continuous mass (Fig. 1), a system of points occupying the centres and angles of these cubes will furnish an example of one of these symmetrical arrangements. In this system each point is equidistant from the eight nearest points, and if a number of equal-sized spheres be stacked on a base layer arranged so that the sphere centres when joined form a system of equal squares, a side of which bears to the diameter of the spheres the ratio $2 : \sqrt{3}$ (see plan *a*), the sphere centres in such a stack will also furnish an example of this first kind of symmetry (Fig. 2).

A second kind of symmetry will be presented if one-half the points in the first kind be removed so that we have only those at the cube centres, or only those at the cube angles. In this system each point is equidistant from the six nearest points, and if equal-sized spheres be stacked upon a base layer, arranged so that the sphere centres when joined form a system of equilateral triangles, a side of which bears to the diameter of the spheres the ratio $\sqrt{2} : 1$ (see plan *b*); and if the layers be so placed that the sphere centres of the fourth layer are over those of the first, those of the fifth over those of the second, and so on, the sphere centres in such a stack will also furnish an example of this second kind of symmetry (Fig. 3).

A third kind of symmetry will be presented if again one-half the points be removed, *i.e.* so that when cubes of two colours arranged in such a way that each cube is surrounded by cubes of the other colour are used (see Fig. 1), we have only the points at the centres of the cubes *of one colour*. In this system each point is equidistant from the twelve nearest points, and if equal-sized spheres be stacked upon a base layer in which the spheres are in contact, and whether they form a square pattern (see plan *c*), or a triangular one (see plan *d*)—provided that, if triangular-pattern layers be employed, the sphere centres in the fourth layer must be over those in the first, those in the fifth over those in the second, and so on—the sphere centres (the arrangement being the same in either case) will furnish a second example of the third kind of symmetry (Figs. 4 and 4*a*, the latter showing a stack with the angle removed to display the triangular arrangement).

A fourth kind of symmetry, which resembles the third in that each point is equidistant from the twelve nearest points, but which is of a widely different character from the three former kinds, is depicted if layers of spheres in contact arranged in the triangular pattern (plan *d*) are so placed that the sphere centres of the third layer are over those of the first, those of the fourth over those of the second, and so on. The symmetry produced is hexagonal in structure and uniaxal (Figs. 5 and 5*a*).

A fifth kind of symmetry, and this completes the number of very symmetrical arrangements possible, resembles the second kind of symmetry in that each point is equidistant from the six nearest points, and bears the same relation to the fourth kind (Fig. 5) as the second (Fig. 3) bears to the third (Fig. 4); that is to say, it may be regarded as produced by the insertion of additional points in positions midway between points arranged in the fourth kind of symmetry. It is depicted if triangularly constituted layers identical with those depicting the second kind of symmetry (plan *b*) are deposited in the following way (Fig. 6):—First place three layers as though to produce the second kind of symmetry; then place the fourth with its sphere centres over those of the second layer; then the fifth so that the third, fourth, and fifth, like the first, second, and third, are in the second kind of symmetry; then the sixth with its sphere centres over those of the fourth and second; and then the seventh, so that the fifth, sixth, and seventh layers are also in the second kind of symmetry; and so on. The symmetry produced is, like the last, hexagonal in structure and uniaxal.

The writer believes that every one of the various symmetrical forms presented by crystals can be shown to be consistent with the subsistence of an arrangement of the atoms of the crystallising compound in one or other of these five kinds of symmetry *at the time when crystallisation begins;* and proposes to show that a relation subsists between the atomic composition of very many bodies and their crystal forms in harmony with this conclusion.

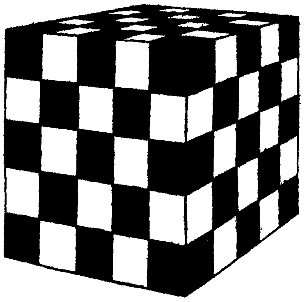

FIG. 1.

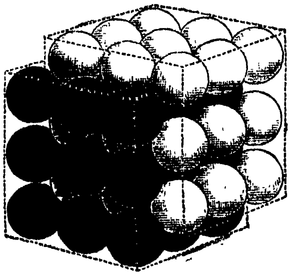

FIG. 2.

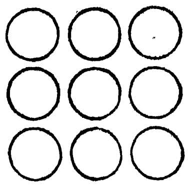

Plan *a*.

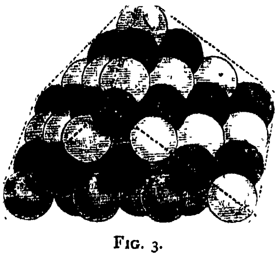

FIG. 3.

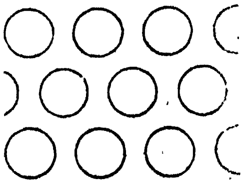

Plan *b*.

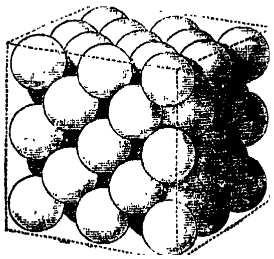

FIG. 4.

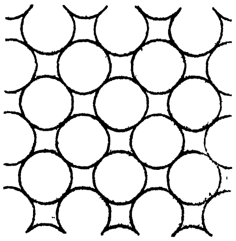

Plan *c*.

To proceed then to facts, we notice first that, as a rule, compounds consisting of an equal number of atoms of two kinds crystallise in cubes.

The following may be mentioned:—

Potassic chloride, KCl.

Potassic bromide, KBr (sometimes elongated into prisms, or extended into planes).

Potassic iodide, KI.
Sodic chloride, $NaCl$.
Sodic bromide, $NaBr$.
Sodic iodide, NaI (anhydrous above 40° C.).
Cæsic chloride, $CS.Cl$.
Plumbic sulphide, PbS.
Argentic chloride, $AgCl$.

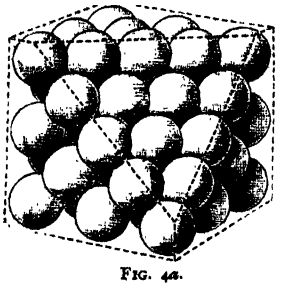

Fig. 4a.

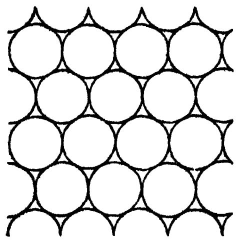

Plan *d*.

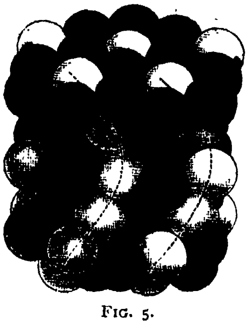

Fig. 5.

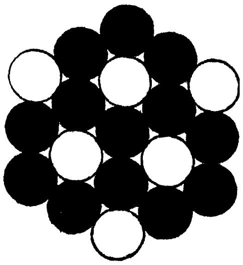

Plan *e*.

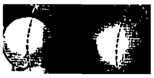

Fig. 5a.

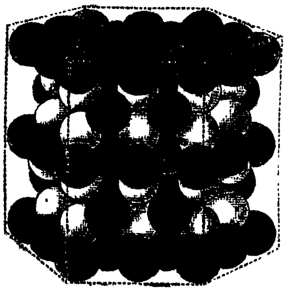

Fig. 6.

Plan *f*.

When we have named lithic chloride, crystallising above 15° in octahedra, we have mentioned most of the compounds consisting of two elements in equal proportions known to us in a crystalline state.

Mercuric sulphide, $Hg.S$, which crystallises in six-sided prisms, is an apparent exception, but if we were guided by the gaseous volume of mercury in determining its atomic weight, we should have to write the compound Hg_2S.

Other apparent exceptions are:—
Zincic oxide, ZnO, crystallising in six-sided prisms.
Cadmium sulphide, CdS; and
Glucina, GO, crystallising in minute six-sided prismatic crystals.

Now three out of our five possible kinds of internal symmetry have three axes or directions at right angles to each other, in reference to which they are disposed in the same symmetrical manner, and two kinds, the first and second, admit of a very symmetrical arrangement of two kinds of particles *in equal numbers* (see Figs. 2 and 3). Surely this coincidence is very significant, and at least suggests the probability that when a compound consists of two kinds of chemical atoms in equal numbers, these atoms are symmetrically placed according to either the first or the second kind of internal symmetry.

We observe next that the third and fourth kinds of symmetry (Figs. 4 and 5) readily lend themselves to the symmetrical arrangement of particles of two kinds present in the proportion 1 : 2. For, as already pointed out, these two kinds of symmetry may either of them be produced by piling up layers of spheres placed triangularly in contact (see plan *d*), and spheres of two colours present in the proportion of 2 : 1 can be arranged in a most symmetrical manner in layers of this kind (see plan *e*).

As to what varieties of position of bi-coloured layers of this kind with respect to one another are possible, consistent with great symmetry, we have concluded that, apart from the question of arrangement of colour, there are but two, viz. the third and fourth kinds of symmetry (Figs. 4 and 5); but taking colour into account a greater variety is possible. Thus a little consideration shows us that, while all the possible ways of depositing the second layer produce a practically identical result, a choice of six different equally symmetrical results is presented in depositing the third layer, in all of which the spheres of the less numerous colour form files of spheres in contact running through the layers, and three of which belong to the third kind of symmetry and three to the fourth.

To specify these: We may have the less numerous spheres of the third layer placed with respect to those in the second and first:—

(1) So that the three spheres of each of the files just above alluded to range in line, the lines joining their centres forming a series of parallel straight lines crossing the planes of the layers obliquely. This arrangement belongs to the third kind of symmetry.

(2 and 3) So that the centres of these three spheres, when joined, form a slightly obtuse angle; a different result being produced as the angle is made to the right or to the left. This pair of arrangements belongs also to the third kind of symmetry.

(4) So that the less numerous spheres in the third layer are vertically over those in the first. This arrangement belongs to the fourth kind of symmetry.

(5 and 6) So that, as in (2) and (3), the triplets of spheres form a system of equal obtuse angles, but the angles now being very obtuse. There are here, as in (2) and (3), a right-handed and a left-handed arrangement. These belong to the fourth kind of symmetry.

The deposition of the third layer, by the necessities of symmetry, determines the deposition of succeeding layers, and it follows therefore from the above that six different equally symmetrical arrangements of spheres of two colours present in the proportion 2 : 1 are possible in the third and fourth kinds of symmetry.

As to (1) the parallel files of the less numerous spheres crossing the first three layers will extend through subsequent layers.

As to (2) and (3) every three continuous layers will display the less numerous sphere centres placed to form the same angles as are presented by the triplets in the first three layers, and consequently these sphere centres lie on spirals which are right-handed or left-handed as the case may be; the less numerous spheres in the fourth layer being vertically over those in the first, those in the fifth over those in the second, and so on.

As to (4) the less numerous spheres in the fourth layer must lie vertically over those in the second, those in the fifth over those in the third, and so on; and thus the files of spheres in contact running through successive layers form a series of similar zigzags.

As to (5) and (6) the sphere centres, as in (2) and (3), lie either on right-handed or on left-handed spirals; in this case the less numerous spheres in the seventh layer being vertically over those in the first, those in the eighth over those in the second, and so on (Figs. 5 and 5*a*).

When we inquire whether the symmetrical arrangements just traced are in harmony with the facts respecting compounds of two kinds of atoms in the proportions 1 : 2, we find some very important evidence.

Thus water, H_2O, crystallises in six-sided prisms or in rhombohedra; forms both of which are compatible with one or other of the above symmetrical arrangements.

And the following most interesting concurrence of facts indicates that the symmetrical arrangements in the fourth kind of symmetry above described (see Figs. 5 and 5*a*) are those of the atoms of quartz.

(*a*) Quartz consists of oxygen two atoms, silicon one atom; just the proportions in these arrangements.

(*b*) It has the property of circular polarisation, from which it has been proved that its molecules must have a *spiral* arrangement, and, since some crystals have the property of rotating in one direction, some in the opposite, that this spiral arrangement is right-handed in some crystals, left-handed in others.

(*c*) It crystallises in six-sided prisms terminated by six-sided pyramids, a form derivable, as we have seen, from the arrangements before us.

As to this last point, just a word of explanation why we must not look for the angles exhibited by our model arrangements to be identical with the angles made by the pyramid faces in quartz.

It is a matter of common observation that the process of crystallisation is generally associated with change of bulk, and if we suppose this change to arise from expansion, or contraction, generally expansion of the different kinds of atoms, and that these different kinds have *different degrees of expansion*, we see that a mass symmetrically arranged in the manner supposed will in crystallising expand or contract more in some directions than in others, and while we should look for a similar change in the direction of each of the three transverse subordinate axes of the crystal, we should look for a different change in the direction of the principal axis. And thus, supposing the mass when liquid immediately before it began to crystallise to have had the internal symmetry which has been depicted, it is evident that the unequal change of dimension in different directions might suffice to bring about such an inclination of the faces of the terminal pyramids to the sides of the prism as is actually found to exist.

In support of this explanation we have the fact that crystals not of the regular system have been found to expand unequally in different directions when subjected to heat.

Further evidence in support of the theories here submitted is found in the fact that, with scarcely any exception, the compounds we are now considering do not crystallise in the regular or cubic system.[1]

WILLIAM BARLOW

(*To be continued.*)

THE HELVETIC SOCIETY OF NATURAL SCIENCES

THE sixty-sixth session of this Society was held early in the month of August of the present year in the city of Zurich. The proceedings of the various Mathematical, Physical, Chemical, Zoological, Botanical, and Medical Departments are somewhat fully reported in the *Archives des Sciences Physiques et Naturelles*, Geneva, October 15. On August 6 a preliminary meeting was held of the delegates of the Cantonal Sections and Special Committees, and next day the session was formally opened in the Town Hall under the presidency of Prof. Cramer. The two ensuing days were devoted to the work of the several Sections, all of which were well attended by numerous Swiss and foreign savants, brought together by the double attraction of the Helvetic Society and the National Exhibition, which was also held this year in Zurich.

In the Mathematical Section, over which Prof. W. Fiedler presided, the chief papers were those of Prof. Geiser (Zurich), on surfaces of the third degree; of Dr. Rudio (Zurich), on the geodetic lines traced on surfaces of the second degree; of Prof. Fiedler (Zurich), on the intersection of equilateral hyperboloids revolving on parallel axes.

In the Physical Section, presided over by Prof. R. Clausius, M. F. A. Forel (Morges) communicated the result of his researches made to determine the limits of variation of temperature in the waters of Lake Geneva. According to his thermometrical soundings, the diurnal variation is perceptible down to a depth of from 10 to 15 metres; the summer variation from 60 to 100 metres. Exceptional winters like that of 1879-80 are felt as low as 334 metres. Since that year the temperature of the water at these great depths has been raised on an average about half a degree Centigrade.

Some preliminary results of his researches on the refraction and dispersion of crystallised alums were communicated by M. Charles Soret of Geneva. By means of his completely reflecting refractometer, described in the *Archives* for January, 1883, the author has determined the indices of refraction for the principal lines of the solar spectrum from *a* to G inclusively for six sulphuric alums with alumina base.

Prof. Clausius read a paper of practical importance on the theory and proper method of construction of dynamo-electric machines. Some curious experiments were made by M. C. de Candolle of Geneva, showing how ripples are formed on sandy surfaces at the bottom of the sea. From these experiments it results that the phenomenon is produced by the friction of a liquid mass against any substance more viscous than itself. Hence the sand may be regarded as forming with the water a viscous mixture, on the surface of which the friction of the pure liquid develops ripples in the same way that the friction of the air develops ripples on the surface of the water itself.

Amongst the other memoirs in the Physical Section the most noteworthy were those of Prof. H. F. Weber (Zurich) on liquids and gases as heat conductors; an experimental demonstration of the second principle of the mechanical theory of heat, by M. Raoul Pictet; on the determination of the ohm, by Prof. H. F. Weber; on the results of the observations and researches made in the laboratory of the Lausanne Academy on atmospheric electricity, by M. Henri Dufour of Lausanne. The author described several successful attempts made by him to reproduce artificially the electric phenomena observed in the terrestrial atmosphere.

The Chemical Section was opened, under the presidency of Prof. Wislicenus, by Prof. V. Meyer's memoir on the nature of the chemical elements according to recent research. The author leans to the views of Mendeleeff and Lothar Meyer, who regard the properties of simple bodies as the periodical functions of their atomic weights. The fact that Mendeléeff was able to predict the existence of gallium and scandium, and correctly determine their atomic weights, was adduced in support of the theory that all the elements are merely different compound forms of one primitive substance. Hence, although hitherto baffled, the attempts now being made to decompose them may result in the experimental determination of one absolute primordial substance.

Prof. F. Krafft (Basle) presented some higher alcohols of the series $C_nH_{2n}+2O$, accompanying them with some remarks on the synthesis of alcohols in general. A *résumé* was given by Prof. Louis Soret (Geneva) of his researches on the absorption of the ultra-violet rays by various substances of animal origin. The author dwelt on the great importance of this branch of spectral analysis to chemistry, and concluded with a brief description of the method and appliances used by him in his original researches.

Other valuable chemical papers were those of Dr. M. Céresole (Lausanne), on acetacetic acids; of Prof. V. Meyer on the apparatus used in determining the densities of gases at very high temperatures; of Prof. Schulze, describing the researches made by him jointly with M. J. Barbieri on phenylamidopropionic acid, which is obtained by heating albuminoid substances with chlorhydric acid and chloride of tin; of Prof. Wislicenus (Wurtzburg), on the relation of the optical rotatory power of carburets of hydrogen, on the existence of an atom of asymmetric carbon, and on the products of the reaction of dichloride of phtalyle on the sodic combination of malonic ether; Prof. G. Lunge (Zurich), on the formation of sulphuric acid in lead chambers; Dr. Urech (Stuttgart), on a lamp fed by ether of petroleum. This lamp, constructed by C. C. Lilienfein, of Stuttgart, consists of a metallic receiver containing the ether of petroleum, and connected with a Bunsen burner slightly modified in consequence of the liquid nature of the combustible.

In the Zoological Section Prof. C. Vogt, president, the proceedings were opened by a communication from Prof. H. Fol (Geneva), on the physiological origin of the individual in the higher animals. M. H. Goll of Lausanne, presented a contribution to the natural history of the sedentary and migratory coregones of Lake Neuchâtel. Memoirs were received on the Arachnidæ of Switzerland by Prof. Pavesi of Pavia; on the fauna of Guatemala, by Dr. Otto Stoll of Zurich; on some new species of Medusæ from the Red Sea, by Dr. Keller of Zurich; on the Pelagic fauna of the Swiss lakes, by Dr. Othmar-Emile Imhof of Zurich; and on the influence of the physico-chemical environments on the development of the tadpole of the edible frog, by M. E. Yung of Geneva. From experiments made by mixing marine salt in various proportions with the natural freshwater element, M. Yung arrived at the conclusion that, the more saline the water, the slower is the development of the tadpole, all transformations ceasing in solutions of 9/1000, and death following in a few hours in solutions of 10/1000.

---

[1] With regard to calcic fluoride (fluor-spar), which appears as an exception, it may be remarked that a different atomic weight for calcium which would enable us to write the compound CaF would enable us to get over a difficulty with regard to another compound of calcium, as we shall see presently.

In the Botanical Section, Prof. Cremer, president, valuable memoirs were received from Prof. O. Heer of Zurich, on the Glacial flora of Switzerland, and on the fossil flora of Greenland. These were the last pages contributed to science by the distinguished savant, who had scarcely finished the revisal of the proofs when he died suddenly at Lausanne, on September 27. A series of hybrids between the *Primula auricula* and *Primula viscosa*, showing an uninterrupted series of forms intermediate between these two species, was exhibited by Prof. Favart of Lausanne. He also showed that the *Cardamine fossicola*, Godet, hitherto classed with the *C. pratensis*, Lin., should be grouped with the *C. matthioli*, Moretti. Some remarks were made by Prof. Schnetzler of Lausanne on a monstrosity of the Chinese primrose, and on the relation between an aërial alga (*Chroolepus umbrinus*) and a lichen (*Pyremula* sp.) M. C. de Candolle described the results of his attempts to determine how far any light may be thrown on the disputed origin of the *Cytisus adami* by the anatomical structure of its leaves. This plant, which suddenly made its appearance in the nursery of Adam at Vitry, near Paris, early in the present century, and which is remarkable for producing red and yellow blossoms mostly on separate branches, is usually regarded as a cross obtained by grafting the *Cytisus purpureus* on the *C. laburnum*. But M. de Candolle concludes that it is not a hybrid, but simply a degenerate variety of the *C. laburnum*.

In the Medical Section, Prof. von Kölliker, president, Prof. Klebs of Zurich read a remarkable paper on the transformations of the human species, which he regards as mainly the result of pathological influences.

Valuable communications were also made on the centres of origin of the optic nerves and on their relation to the cerebral cortex, by Dr. C. von Monakow of St. Petersburg; on the relations existing between the excitability and vulnerability of certain muscular groups, by Prof. Luchsinger of Berne; and on the mechanism of the ruminating process, by the same author.

The report on the Geological Section was unavoidably postponed to the November issue of the *Archives*.

NOTES FROM THE OTAGO UNIVERSITY MUSEUM

IV.—*On the Structure of the Head in "Palinurus," with special reference to the Classification of the Genus*[1]

THE genus *Palinurus* was divided by Milne-Edwards into two groups or sub-genera—one, the "Langoustes ordinaires," containing species in which the antennulary flagella are short, the bases of the antennæ approximated, and the rostrum present; while the other, or "Langoustes longicornes" (*Panulirus*, Gray; *Senex*, Pfeiffer), contains species in which the antennulary flagella are short, the antennæ widely separated at their proximal ends, and the rostrum absent.

In this classification, which is still in the main adopted by systematists, no notice is taken of the stridulating organ, first mentioned, I believe, by Leach, in *P. vulgaris*, and described at length by Möbius, and later by myself, in the same species.[2] This unique sound-producing apparatus is present in all the "Langoustes longicornes" which I have yet examined, as well as in *P. vulgaris* and *P. trigonus* among the "Langoustes ordinaires"; while in all the remaining members of the latter group which have come under my notice (*e.g.* the common New Zealand species, *P. lalandii* and *P. edwardsii*) there is no trace of it.

There is also great diversity among the "Langoustes ordinaires" in the development of the rostrum, the true size of which can only be seen in a longitudinal vertical section of the head (see Fig. 1). In *P. lalandii* and other non-stridulating species, the rostrum (A, *r*) is well developed, and bears comparison with that of *Homarus*, while in *P. vulgaris* (B, *r*) it is a mere spiniform tubercle meriting special description only from its position. *P. vulgaris*, moreover, has no trace of procephalic processes, which are present, though small, in *P. lalandii* (A, *pc.p*).

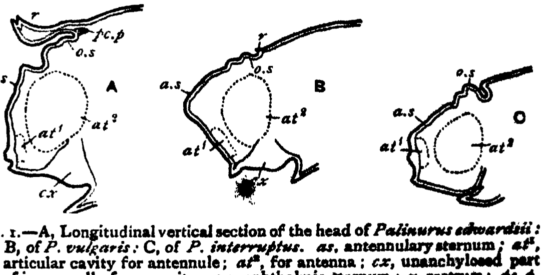

FIG. 1.—A, Longitudinal vertical section of the head of *Palinurus edwardsii*: B, of *P. vulgaris*: C, of *P. interruptus*. *as*, antennulary sternum; at^1, articular cavity for antennule; at^2, for antenna; *cx*, unanchylosed part of inner wall of coxocerite; *o.s*, ophthalmic sternum; *r*, rostrum; *pc.p*, procephalic process.

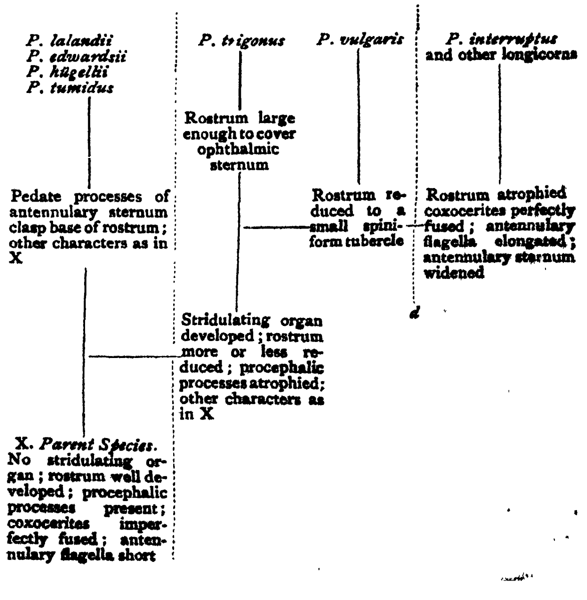
The woodcut shows that as regards both the rostrum and the antennulary sternum (the fixed part of the stridulating organ), *P. vulgaris* (B) approaches far more nearly to the "Langoustes longicornes," as represented by *P. interruptus* (C), than to the non-stridulating "Langoustes ordinaires," as represented by *P. edwardsii* (A).

On the other hand, all the brevicorn species examined agree in the imperfect fusion of the coxocerites or proximal segments of the antennæ. A transverse section taken immediately in front of the renal apertures shows that a small portion of the adjacent or inner walls of the coxocerites in *P. lalandii*, *P. vulgaris*, &c., are merely in apposition, whereas in the longicorn species concrescence is complete.

Assuming that the *Palinuridæ* are derived from an Astacoid or Homaroid ancestor through some such intermediate form as *Palinurellus*, one cannot but conclude that the species which have no stridulating organ, a well-developed rostrum, procephalic processes, and imperfectly fused coxocerites, come nearest to the parent stock, and that those in which the stridulating organ is developed, the rostrum and procephalic processes absent, and the coxocerites completely united with one another, have diverged most from that stock, and present us with the extreme of modification of the Palinuroid type.

This view is expressed in the following phylogenetic table:—



P. lalandii
P. edwardsii
P. hügelii
P. tumidus
P. trigonus
P. vulgaris
P. interruptus and other longicorns
Rostrum large enough to cover ophthalmic sternum
Pedate processes of antennulary sternum clasp base of rostrum; other characters as in X
Rostrum reduced to a small spiniform tubercle
Rostrum atrophied coxocerites perfectly fused; antennulary flagella elongated; antennulary sternum widened
d
Stridulating organ developed; rostrum more or less reduced; procephalic processes atrophied; other characters as in X
X. Parent Species.
No stridulating organ; rostrum well developed; procephalic processes present; coxocerites imperfectly fused; antennulary flagella short

---

[1] Abstract of a paper taken as read at a meeting of the Otago Institute, September 12, 1883, and to be published in the next (16th) volume of the *Transactions of the New Zealand Institute*.

[2] Leach, "Malacostraca podophthalmata Britanniæ": Möbius, *Archiv für Naturgeschichte*, 1867; T. J. Parker, *Proc. Zool. Soc.*, 1878, p. 442.

In a natural classification of the genus the most fundamental separation appears to me that along the dotted line *a b* dividing the non-stridulating from the stridulating species. This division once made, the stridulating species fall into two natural subdivisions, expressed in the table by the line *c d*, which divides the brevicorn from the longicorn forms.

I think the most convenient classification is obtained by dividing the species along the two lines *a b*, *c d* into three sub-genera, one identical with the "Langoustes longicornes" of Milne-Edwards, the others formed by splitting up the "Langoustes ordinaires" into species with and species without a stridulating organ.

The following table embodies the proposed arrangement:—

Genus PALINURUS, Fabr.

A. Stridulating organ absent; rostrum well developed, clasped by paired pedate processes of the antennulary sternum; procephalic processes present; coxocerites imperfectly fused; antennulary flagella short (sub-genus *Jasus*, T.J.P.).
P. lalandii, *P. edwardsii*, *P. hügellii*, *P. tumidus*.

B. Stridulating organ present; rostrum variable, but rarely (? never) as well developed as in (A); pedate clasping processes absent; procephalic processes absent.
- *a.* Antennulary sternum narrow below, bases of antennules being hidden, in a view from above, by bases of antennæ; coxocerites imperfectly fused; antennulary flagella short (sub-genus *Palinurus*).
  - *α.* Rostrum well developed, covering ophthalmic sternum. *P. trigonus.*
  - *β.* Rostrum reduced to a small spiniform tubercle; ophthalmic sternum uncovered. *P. vulgaris.*
- *b.* Antennulary sternum broad below, bases of antennules being visible from the dorsal aspect; coxocerites perfectly fused; antennulary flagella long (sub-genus *Panulirus*, Gray; *Senex*, Pfeiffer).
P. interruptus, *P. fasciatus*, &c., &c.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 6.—"The Wave-lengths of A, *a*, and of some Prominent Lines in the Infra-Red of the Visible Spectrum." By Capt. Abney, R.E., F.R.S.

M. Fievez has recently sent the author a map of the solar spectrum from C to A ("Annales de l'Observatoire Royal de Bruxelles," nouvelle série, tome v.) inclusive, and as part of this region is one which he is measuring, he examined the new publication with great interest. Photography and eye measurements do not coincide in the detail of the grouping of the little *a* group, or from there as far as A, and A itself is shown by M. Fievez's map as wanting in some details which appear in the photographs. The wave-lengths of the different lines from above "*a*" to A are not those given by Fievez, when comparison photographs of the 1st order of the red with the 2nd of the ultra-violet were taken on the same photographic plate, or when the 2nd order of the red is compared with the 3rd order of the green taken in a similar manner. Prof. Rowland's concave gratings were employed for this comparison. Cornu's map was used as a reference for the ultra-violet wave-lengths, and Ångström's map for those in the blue and green.

Description of line	λ from comparison of 1st and 2nd orders	λ from comparison of 2nd and 3rd orders	λ according to Fievez	Remarks
"*a*" ………	7184·4 7185·4	7184·5 7185·4	7197·7 7198·7	This is shown in Ångström's map as a single line λ 7184·9.
Most refrangible edge of A.	7593·6	7593·7	7600·0	Ångström gives 7604 for the centre of this line; which of the bands he took as A is not clear. Langley gave 7600·9 for this edge.
Centre of 6th pair of lines in the flutings following A.	7644·2	7644·33	7652·2	

The determination of A has been made by Mascart, Smythe, and others, besides Ångström and Langley, with discordant results. The above may be taken as accurate, as are Cornu's and Ångström's maps.

The following are wave-lengths of some of the principal lines in the infra-red. The scale numbers refer to the author's map of the infra-red, which is published in the *Phil. Trans.*, Part II., 1880:—

Scale number	Description	Wave-lengths
1046	This line is a double, of which the components have the accompanying wave-lengths……	8226·4 8229·9
1441	…………………	8496·8
1509	…………………	8540·6
1685	…………………	8661·0
2175	A double line, the components of which have the accompanying wave-lengths ……………	8986·2 8989·5
2638	" " "	9494·5 9500·1
3161	…………………	9633·8

Mathematical Society, December 13.—S. Roberts, F.R.S., vice-president, in the chair.—The following were elected members:—Messrs. A. B. Basset, H. Fortey, R. T. Glazebrook, F.R.S., G. Heppel, J. J. Thomson, H. H. Turner, and Prof. W. Thomson, Cape Colony.—The following papers were communicated:—The form of standing waves on the surface of running water, by Lord Rayleigh, F.R.S.—A method of finding the plane sections of a surface and some considerations as to its extension to space of more than three dimensions, by Mr. W. J.

C. Sharp.—On a deduction from the elliptic-integral formula $y = \sin (A + B + C \ldots)$, by Mr. J. Griffiths.

Linnean Society, December 6.—Sir John Lubbock, Bart., president, in the chair.—H.H. Maharajah of Travancore, and Messrs. C. A. Barber, E. Bostock, H. Friend, J. Hannington, J. S. Hicks, J. Richardson, R. Tate, and H. Tisdall were elected Fellows of the Society.—Mr. B. Daydon Jackson exhibited a specimen of "Mexican whisks," known also in the London market as "chien-dent," which are now imported in considerable quantity from the vicinity of La Puebla in Mexico. It is believed to be derived from a species of *Andropogon*, but is in bulk coarser than the similar material from Southern Europe from *Andropogon gryllus*, and finer than the species of *Panicum* used in India for brushes.—Mr. Arthur Bennett exhibited a specimen of *Carex ligerica* gathered by Mr. Cunnack on the Scilly Isles (Cornwall), and believed by him to be a sterile form of *C. arenaria*, but identified as *C. ligerica* by Prof. Babington, and therefore new to science. Mr. Bennett also drew attention to locally so-called "vegetable hedgehogs," these being agglomerated larch leaves (having some resemblance to a rolled hedgehog) found in the Shropshire meres.—A large number of Lepidoptera from the district of Georgetown, Colorado, and a few from Missouri were exhibited by Mr. Ernest Jacob, who had collected them while engaged in the U.S.A. Geological Survey in the above districts, 1880-81.—A series of dried plants from Australia were shown on behalf of Mr. James Robertson. —Mr. Charles Darwin's paper on instinct (noticed in our last week's issue) was then read by the Zoological Secretary, and an important discussion followed, in which Mr. Wallace, Profs. Huxley, Allman, Mivart, Foster, Lankester, Mr. McLachlan, Mr. Seebohm, and others took part.

Zoological Society, December 4.—Prof. W. H. Flower, F.R.S., president, in the chair.—Mr. Philip Crowley, F.Z.S., exhibited and made remarks on an egg of a Bower-bird from Southern New Guinea, supposed to be that of *Chlamydodera cerviniventris*.—Sir Joseph Fayrer, F.Z.S., exhibited a shed deer-horn, apparently gnawed by other deer, and made remarks on this subject.—Mr. Sclater exhibited, on the part of Dr. George Bennett, F.Z.S., four skins of a species of Paradise-bird of the genus *Drepanornis*, obtained in the vicinity of Port Moresby in Southern New Guinea. Mr. Sclater considered this form to be only subspecifically different from *D. albertisi* of North-eastern New Guinea.—Mr. W. Burton, F.Z S., exhibited a supposed hybrid between a male blackcock and a hen pheasant. —Mr. R. Bowdler Sharpe gave descriptions of some new species of Flower-peckers, viz. :—*Dicæum sulaense*, from the Sula Islands; *D. pulchrius*, from South-eastern New Guinea; and *D. tristrami*, from the Solomon Islands. The author added some critical notes on other species of *Dicæum* and *Prionochilus*.—Mr. J. B. Sutton read a paper on the diseases of monkeys dying in the Society's Gardens, on which he gave many interesting details. Mr. Sutton called special attention to the prevalence of the belief that monkeys in confinement generally die of tuberculosis, and showed that such is not really the case.—Mr. H. O. Forbes, F.Z.S., read a paper describing the peculiar habits of a spider (*Thomisus decipiens*) as observed by him in Sumatra.—A second paper by Mr. Forbes gave an account of some rare birds from the Moluccas and from Timor Laut. To this the author added the description of a new species of Ground-Thrush from Timor Laut, which he proposed to call *Geocichla machiki*, in acknowledgment of services rendered to him by Dr. Julius Machik in Sumatra.—A communication was read from Prof. J. von Haast, F.R.S., containing notes on *Ziphius* (*Epiodon*) *novæ-zealandiæ*, in continuation of a former paper read before the Society on the same subject.—A second communication from Prof. Haast gave a description of a large Southern Rorqual (*Physalus* (*Balænoptera*) *australis*) which had been washed ashore dead on the New Brighton beach about five miles from Christchurch, New Zealand. Prof. Haast was doubtful as to the distinctness of this animal from *Balænoptera musculus* of the Northern Atlantic.—Mr. G. French Angas, C.M.Z.S., read some notes on the terrestrial Mollusca of Dominica collected during a recent visit to that island.

Mineralogical Society, December 11.—The Rev. Prof. Bonney, president, in the chair.—The following papers were read :—On some specimens of lava from Old Providence Island, by the President.—On the evidence of the occurrence of nickel iron with Widmanstätten's figures in the basalt of North Greenland, by Prof. K. T. V. Steenstrup.—Note on a new mode of occurrence of garnet, by H. Louis.—A chemical examination of the Greenland telluric iron (translated from "Medelel-er fra Grönland," Heft 4, 1883), by Joh. Lerenzon.—At 9 p.m. (pursuant to notice) the meeting was made special, and the members of the Crystallographical Society were elected members of the Society, a portion of the rules relating to election being for the time suspended.

DUBLIN

University Experimental Science Association, Nov. 13. —Prof. V. Ball in the chair.—On the magnetophone, by Prof. Fitzgerald. A new form of the instrument was exhibited by W. V. Dixon. In this a diaphragm removed from a telephone is placed in close proximity with one extremity of a bar magnet, at the other extremity of which small masses of soft iron fixed radially on an axle are rotated. A note is produced at the diaphragm.—On the phenomena attending pressure on sensitive plates, by W. Hogg. Experiments confirmatory of those described by Capt. Abney were made, and enlarged photos of the developed marks shown. Similar experiments on sensitive albuminised paper were described by P. M. Crosthwaite; the use of paper allowed of considerable pressure being applied.—On compound locomotives, by F. Trouton.—On the identification of minerals by means of their specific heats, by J. Joly.—On the deposition of metallic copper in cracks, by N. M'J. Falkiner.—Experiments gave results similar to those obtained by Becquerel.

MANCHESTER

Literary and Philosophical Society, November 27.—H. E. Roscoe, F.R.S., president, in the chair.—On the fungus of the salmon disease—*Saprolegnia ferax*, by H. Marshall Ward, M.A., Fellow of Christ College, Cambridge.

PARIS

Academy of Sciences, December 10.—M. Blanchard, president, in the chair.—Note on a new compound of rhodium, by M. H. Debray.—On the quantities forming a group of nonions analogous to the quaternions of Hamilton, by M. J. Sylvester.—Summary report on the geological, botanical, zoological, and anthropological work accomplished by the French mission to Cape Horn, by Dr. Hyades. In the southern islands of the Fuegian Archipelago the prevailing rocks were found to be schists and granites greatly weathered wherever unprotected by vegetation. The dwarf Antarctic beech is limited to an altitude of 400 metres, the *Fagus betuloides* to 300, forming with the Drimys and Berberis a forest zone with a humid soil poor in vegetable humus, and covered with mosses, heaths, and a considerable variety of small plants. The marine flora abounds in all kinds of algæ (the most common being the *Macrocystis pyrifera*), affording a shelter to numerous zoophytes, Annelidæ, mollusks, Crustaceæ, and migratory fishes of eight or ten species. Of the shell-fish, which abound on most of the seaboard, all the large species are edible. Although poorer than the marine, the land fauna includes several species of Coleoptera, Lepidoptera, Arachnidæ, some forty species of birds, but no reptiles or frogs. The mammals are represented only by one species of fox, two rodents, and an otter, besides the domestic dog. The natives all belong to the Tekeenika stock of Fitzroy, called Yahgans by the present English missionaries. They speak an agglutinating language current from the middle of Beagle Passage to the southernmost islands about Cape Horn. About 1000 words of this language were collected, including some abstract terms, such as *tree, flower, fish, shell.* The numerals get no further than *three*, although the natives count also on the fingers. Over a hundred anthropometric observations were taken on individuals of all ages and both sexes. Good photographs were also obtained of a large number of Fuegians, besides numerous castings of all parts of the body, some skeletons, and a great variety of ethnological materials.—Note on the *Phylloxera gallicola*, by M. F. Henneguy.—Observations on the new planet 235 made at the Observatory of Paris (equatorial of the west tower), by M. G. Bigourdan.—Observation of the spectrum of the comet Pons-Brooks, 1812, at the 14-inch equatorial (0·378 m.) of the Bordeaux Observatory, by M. G. Rayet.—On the form of the expressions of the mutual distances in the problem of three bodies, by M. A. Lindstedt.—On the number of the permutations of n elements presenting s sequences, by M. D. André.—Note on a theorem of Liouville, by M. Stieltjes.—New demonstration of two theorems of M. Bertrand, by M. Georges Ossian Bonnet.—Formulas giving the electric resistance of the circuit employed in the Edison system of electrical lighting, by M. G. Guéroult.—Observations relative to a method of studying earth currents, in connection with a communication recently made by M. Blavier, by M. F. Larroque.—Researches on the solidification of superfused sulphur (second part), by M. D. Gernez.—Determination of the equivalent of aluminium by means of its sulphate, by M. H. Baubigny.—On the formation of acetylene at the expense of the iodoform, by M. P. Cazeneuve.—New researches on the susceptibility of the eye to differences of luminous intensity, by M. Aug. Charpentier.—Cholera, small-pox, typhoid fever, and charbon amongst the coppersmiths of Villedieu, by M. Bochefontaine. Although the whole atmosphere of the place is, so to say, saturated with copper, nine of the inhabitants of Villedieu, all engaged in the copper industry, fell victims to cholera in 1849. Considering the difference of population, this would represent a mortality of 5700 in Paris. Nearly half of the population was attacked by small-pox in 1870, and a fatal case of charbon occurred in 1865.—On the existence and distribution of eleidine in the bucco-œsophagian mucous membrane of mammals, by M. L. Ranvier.—On the genus Verquia, a fossil yew found in the Aachen formations of Tournai, by M. C. Eg. Bertrand.—On a luminous phenomenon observed after sunset at Amiens on several evenings about the end of November and beginning of December last, by M. Decharme. The author feels inclined to attribute these effects to the aurora borealis. Details of similar manifestations observed in other places were quoted from a recent number of NATURE.

BERLIN

Physical Society, November 30.—Dr. Kayser placed before the meeting a concave grating sent by Prof. Rowland to the Physical Institute, explained the principle of this apparatus, and exhibited a photograph of the normal spectrum produced by help of the grating, as also a negative prepared by Prof. Rowland, on which Dr. Kayser was able with the naked eye to count between the two H lines over seventy fine lines, among which some appeared to form groups, so that by means of a microscope many more lines still would be distinguishable.—Prof. von Helmholtz next gave a minute report of the continuation of the experiments he had instituted with a view to explaining galvanic polarisation according to thermodynamic principles. Suppose that an electric current passed through a liquid completely free of gas, then would the gases generated by decomposition of the electrolyte be first absorbed by the liquid, and only after the latter was saturated to a degree corresponding with the pressure of gas resting on it would the development of gas begin. The previous solution of gas in the liquid was the expression of an attraction or of a molecular energy between the water and the gas, which acted in the same direction as did the electromotive energy which decomposed the electrolyte at the electrode. The absorption of the gas, therefore, agreeably with the teaching of the mathematical theory, increased the electromotive energy, and all the more so the less gas the liquid contained. This accorded with the experience derived from experiments that the convective current was so much the stronger by how much the less gas the fluid had absorbed. If the liquid already contained gas in solution, a part of it would escape at the surface by a kind of dissociation, and form above the liquid an atmosphere the pressure of which corresponded with that of the momentary saturation of the liquid. This dissociation of the solution represented a work which could reciprocally be applied to the conversion of gas to a liquid state; that is to say, supposing the conditions were such that the temperature of the system was maintained throughout unaltered, the whole process was a reversible one. With this consideration let one start from any normal condition whatsoever, from atmospheric pressure for example, then it was the teaching of the theory that the work was all the greater the less was the quantity of gas in solution, and in the case of very small gas volumes the work would be endless, that is to say, in every fluid were dissolved minute quantities of gas which could no longer be discharged. If the electrolytic fluid contained oxygen in solution, as in fact was regularly the case, the oxygen would be drawn by convection towards the oxygenous electrode, and there augmented by the oxygen which had been electrolytically separated, and after loss of its electricity become neutral. The gas would now begin to diffuse itself towards the other, the hydrogenous electrode, and this diffusion would produce the polarisation current which, just as much as the diffusion stream, was opposed to the electrolytic current and convection. The quantity of oxygen in the fluid and its diffusion might be illustrated by a curve which ascended from the hydrogenous electrode as its zero point rectilinearly to the oxygenous electrode, and so long as the electromotive force remained the same at the electrodes a state of equilibrium was maintained between electromotive force, convection, polarisation current, and diffusion; a state of equilibrium which was disturbed when the current was interrupted for however short a time. The theory of these processes taught, what experience confirmed, that a much greater electromotive force was required after the interruption to re-establish electrolysis than was before needed to continue the process. If the fluid were saturated with gas to a degree corresponding with the pressure of gas resting on it, the gases generated by electrolysis escaped. Seeing, however, that the degree of saturation was dependent on the pressure of gas, therefore, with the increase of gas pressure, the electromotive force which caused the development of gas would likewise have to be increased. It was now sought to ascertain the least electromotive force that was sufficient under a definite pressure to cause a development of gas, and the experiments made with this object in view showed that the development of the first bubbles had to overcome a considerable resistance, and therefore demanded intenser currents than were needed for later gas bubbles. When, by a definite current through an extended metallic wire, gas was developed in an electrolyte, by lessening the electromotive force it was possible to produce only single gas bubbles at one point of the wire. The same amount of electromotive force which was sufficient to produce this effect was not, however, equal to the generation of bubbles from the outset. To effect this latter result, a much stronger current would have to be employed. All these processes and relations here briefly indicated were mathematically calculated, and the results of the experiments invariably coincided with the teachings of the theory.

VORTEX RINGS

The Motion of Vortex Rings. By J. J. Thomson. (London: Macmillan and Co., 1883)

BOTH as regards the interest of the subject and the treatment it has received at the hands of the author we do not doubt that the essay before us is destined to take a foremost place amongst the essays which have been called forth, or at all events distinguished, by the Adams Prize.

The fact that these essays are upon set subjects precludes the possibility of the prize being awarded for a distinctly original conception. It is almost a necessity that the subjects chosen should involve the extension of some mathematical investigation which has already been carried a certain length.

The subject of the present essay is distinctly of this class; it involves an extension of the investigation of the theory of vortex motion in an ideal fluid, founded by Helmholtz and continued chiefly by Sir William Thomson.

At the time Helmholtz conceived the fundamental principle, ideal hydrodynamics had no other interest, besides its mathematical interest, than it derived from the somewhat casual explanations it affords of the phenomena met with in the motion of actual fluids. Helmholtz's investigation had some relation to the observed phenomena of actual vortices, particularly to the phenomena of smoke rings, of which it afforded a general explanation. But between the fundamental equations which Helmholtz gave and their application to an actual vortex ring certain integrations were necessary, and these integrations presented mathematical difficulties. If we consider the line of smoke which forms the ring as indicating the portion of air in which vortex motion exists, we may say that the difficulties of integration at which Helmholtz stopped arise from the thickness of this line of smoke, or, calling this the circular core of the ring, from the finite area of the section of this core. Helmholtz contented himself with applying his theory to an indefinitely thin core; and the fact that the results of a theory based on a frictionless fluid would only have an imperfect relation to the motions of viscous fluids, together with the fact that such rings, although they may be produced by artificial apparatus, are short-lived, and have no existence in the general motion of fluids, offered but little inducement for farther prosecution of the subject. The case however was altered when it was conceived by Sir William Thomson that the atoms of matter may be such rings moving in a perfect universal fluid. Smoke rings, although their behaviour seems to have suggested the idea, could not, owing to the viscosity of the air, by any means be made to afford an experimental verification of the capabilities of such an hypothesis. The only way was to integrate Helmholtz's equations, and thus arrive at the theoretical behaviour of such rings. Unfortunately the mathematical difficulties are such that there is little hope of obtaining a complete theory of vortex rings having cores of any finite area. Sir William Thomson, however, started an approximate theory as a step towards this; he succeeded in approximately integrating the equations for rings the cores of which had sections finite but small compared with the openings of the rings, and with such rings it appears that his theory can be tested as regards matter in the gaseous state.

To do this, however, it is necessary to do more than work out the theory of a single circular ring having a core of circular section. The phenomena of gases depend on the internal vibration of the atoms and on the influence which they exert on each other by collisions or otherwise. It was necessary therefore to obtain the theory of the vibrations of these rings, also of the effect of what may be called collisions.

Sir William Thomson took many steps towards the theory of vibrations. But the theory of collisions was left for Mr. J. J. Thomson.

Mr. Thomson has not, however, confined his attention to the point set for the prize, but, starting from the foundation laid by Helmholtz, has recast the theory to his own method.

Having deduced general expressions for the momentum, moment of momentum, and energy in a mass of fluid in which there is vortex motion, which expressions are better adapted for his purpose than any previously obtained, he proceeds to the theory of a solitary vortex ring subject to the same limitation as that treated by Sir William Thomson, *i.e.* the diameter of the core small compared with the opening of the ring, but of more general shape, in that it may have any small deviation from the circular form. He obtains results which, where they correspond, agree very approximately with those previously obtained by Sir William Thomson.

The author then proceeds to the immediate subject of the essay—the action upon each other of two rings.

In dealing with this subject he introduces another important limitation, *i.e.* that the rings shall not approach each other by a distance which is large compared with the openings of the rings.

With this limitation, by means of a very powerful piece of mathematical work, the theory of the mutual action of such rings is deduced, both as regards mean motion and vibration; and he has thus carried the theory of vortex atoms to such a stage that in certain general respects it can be applied to the theory of gases.

The essay, however, does not end here, for, although outside the set subject, the author proceeds to consider the theory of "linked rings." This term does not seem well chosen, for it conveys the idea of rings linked as in a chain, whereas what it is used to express is a ring of which the core is compounded of several separate cores wrapped in a spiral manner round each other like a ring composed of twisted wire.

In the treatment of this branch of his subject he has been no less successful than in the earlier parts.

From the general scheme of his essay it is clear that the author has had in his mind as a general object the verification of the vortex atom theory; and although he avowedly refrains from going at length into such a vortex atom theory of gases as might be built upon his work, he adds a chapter at the end in which he discusses certain results of his work, which may be applied without further calculation to the vortex atom theory of gases.

It is this chapter which will excite the most general interest, for although the fact of this still very incomplete theory being found consistent with observed gaseous phenomena would not afford a crucial test of its fitness to explain the phenomena of solids and liquids, still its failure to explain the phenomena of gases would appear to be crucial as regards its unfitness as an atomic theory.

The fair and cautious spirit in which Mr. Thomson discusses his results cannot be too much admired, although we may not be quite able to realise the truth of his reasoning.

The most general and important phenomenon of gases is that sometimes called Boyle's law—that the product of the volume and pressure of any fixed weight of gas varies directly as the amount of heat, *i.e.* kinetic energy, in a gas.

Accordingly Mr. Thomson calculates the product of the pressure and volume which would result in the case of a vortex atom gas. This he finds equal to two terms, one being the kinetic energy multiplied by a constant, the other a certain quantity which involves the squares of the velocity of the medium at the boundary surface. To fit Boyle's law this second term must vanish or nearly so. Mr. Thomson argues that it does so vanish, because the surface being at rest the velocity of the fluid at it must be small. This argument we entirely fail to follow, possibly owing to some misapprehension on our part; but it seems to us that a vortex being near a solid surface is no reason for supposing the tangential velocity of the fluid small, while if the gas consists of vortex atoms so must the solid surface, and there is nothing to show that the mean square of the velocity within the solid and at its surface will be less than in the gas.

Passing on from Boyle's law, with the explanation of which he is satisfied, the author next turns to the phenomena depending on the velocity of the gaseous molecules. As this seems to us the most interesting part of the discussion, we quote the passage in full:—

> "According to the vortex atom theory, as the temperature rises and the energy increases the mean radius of the vortex rings will increase, but when the radius of a vortex ring is increased its velocity is diminished, and thus the mean velocity of the molecules decreases as the temperature increases; thus it differs from the ordinary kinetic theory, where the mean velocity and the temperature increase together. It ought to be remarked, however, that though in the vortex atom theory the mean velocity decreases as the temperature increases, yet the mean momentum increases with the temperature.
>
> "The difference between the effects produced by a rise in temperature on the mean velocity of the molecules will probably furnish a crucial experiment between the vortex atom theory and the ordinary kinetic theory of gases, since all the laws connecting the phenomena of diffusion with the temperature can hardly be the same for the two theories. In fact, if we accept Maxwell's reasoning about the phenomenon called 'thermal effusion' we can see at once an experiment which would decide between the two theories.
>
> "The phenomenon is this, if we have a porous diaphragm immersed in a gas, and the gas at the two sides of the diaphragm at different temperatures, then when things have got into a steady state the pressures on the two sides of the diaphragm will be different, and Maxwell, in his paper 'On Stresses in Rarefied Gases' (*Phil. Trans.* 1879, part i. p. 255), gives the following reasoning to prove that, according to the ordinary theory of gases, the pressures on the two sides are proportional to the square root of the absolute temperatures of the sides. He says:—
>
> "'When the diameter of the hole and the thickness of the plate are both small compared with the length of the free path of the molecule, then, as Sir W. Thomson has shown, any molecule which comes up to the hole on either side will be in very little danger of encountering another molecule before it has got fairly through to the other side.
>
> "'Hence the flow of gas in either direction through the hole will take place very nearly in the same manner as if there had been a vacuum on the other side of the hole, and this whether the gas on the other side of the hole is of the same or of a different kind.
>
> "'If the gas on the two sides of the plate is of the same kind but at different temperatures, a phenomenon will take place which we may call *thermal effusion.* The velocity of the molecules is proportional to the square root of the absolute temperature, and the quantity which passes out through the hole is proportional to this velocity and to the density. Hence, on whichever side the product of the density into the square root of the temperature is greatest, more molecules will pass from that side than from the other through the hole, and this will go on till this product is equal on both sides of the hole. Hence the condition of equilibrium is that the density must be inversely as the square root of the temperature, and since the pressure is as the product of the density into the temperature, the pressure will be directly proportional to the square root of the absolute temperature.'
>
> "If we were to apply the same reasoning to the vortex atom theory, we should no longer have the velocity proportional to the square root of the absolute temperature, but to some inverse power of it, and the above reasoning would show that if p and p' be the pressures, t and t' the temperatures on the two sides of the plate, $p/p' = (t/t')^m$, where m is a quantity greater than unity. Thus accurate investigations of the phenomenon of thermal effusion would enable us to decide between the vortex atom and the ordinary kinetic theory of gases. These experiments would, however, be difficult to make accurately, as we should have to work with such low pressures to get the mean path of the molecules long enough that the pressure of the mercury vapour in the air-pump used to rarefy the gas might be supposed sensibly to affect the results. In the theoretical investigation, too, the effects of the bounding surface in modifying the motion of the gas seem to have scarcely been taken sufficiently into account to make the experiment of the crucial test of a theory; and it is probable that the theory of the diffusion and viscosity of the gases worked out from the laws of action of two vortex rings on each other, given in Part II. of this essay, would lead to results which would decide more easily and more clearly between the two theories.
>
> "The preceding reasoning holds only for a monatomic gas which can only increase its energy by increasing the mean radius of its vortex atoms; if, however, the gas be diatomic, the energy will be increased if the shortest distance between the central lines of the vortex cores of the two atoms be diminished, and if the radius of the vortex atom is unaltered the velocity of translation of the molecule will be increased as well as the energy; thus for a diatomic molecule we cannot say that an increase in the energy or a rise in the temperature of the gas would necessarily be accompanied by a diminution in the mean velocity of its molecules."

With the argument here used we have no fault to find, but it does seem to us that the author has fallen into some confusion between the experimental phenomenon of thermal transpiration through porous plugs and the theoretical idea of "thermal effusion." It has probably escaped Mr. Thomson, but the experiment he suggests was included in the general investigation, made by the writer of the present review,[1] by which the phenomenon of thermal transpiration was discovered, and although it still appears that these are the only experiments on this subject, yet they conclusively prove that the difference of the pressure on the two sides of the plate is proportional to the square roots of the absolute temperatures. So far then it would seem that the crucial experiment has been made and that the verdict is against the vortex atom theory; but this is not so, for, although the experiment Mr. Thomson suggests has been made, it is definitely and experimentally shown in the same investigation that the action of the porous plug is entirely different from that which Maxwell calls thermal effusion, being due entirely to the tangential action of the walls of the passages, and further this tangential action is in strict accordance with the present dynamical theory of gases. This experiment with the porous plug, then, affords no test whatever in the way suggested by Mr. Thomson. Mr. Thomson has, we think, been unfortunate in his choice of tests; and we would suggest *the velocity of sound* as affording a crucial test for which the experimental work is already done. It appears to be an almost obvious deduction from the vortex atom theory that the velocity of sound must be limited by the mean velocity of the vortex atoms; and since Mr. Thomson has shown that this mean velocity diminishes with the temperature, while experimentally it is found that the velocity of sound increases as the square root of the temperature, it appears that the verdict must be against the vortex atom theory. However the vortex atoms are very slippery things, and we should like to hear Mr. Thomson's opinion before adopting one of our own.

Besides discussing the theory of gases, Mr. Thomson goes somewhat fully into a vortex atom theory of chemical combinations; in this he raises many points which will doubtless be of great interest should the hypothesis survive the crucial test by the theory of gases which this essay now for the first time renders possible.

Of the mathematical interest of the essay we can only say that to those who can appreciate it this will be found to be very great.

OSBORNE REYNOLDS

OUR BOOK SHELF

Krystallographische Untersuchungen an homologen und isomeren Reihen. Von Dr. A. Brezina. I. Theil. Methoden. (Wien, 1884.)

THIS very useful volume forms an introduction to the author's crystallographic investigations which earned the prize of the Vienna Academy. It deals exclusively with the principles and the methods employed in those investigations, and constitutes a complete storehouse of the formulæ required in the study of crystals, and of the best means of applying those formulæ. The following subjects are successively treated: the optical principles involved in the goniometer; the practical use of the instrument, and the errors to which it is liable; the criticism of probable errors of observation; stereographic projection; all possible cases of trigonometrical calculation, including the method of least squares; and a slight sketch of the use of the polarising apparatus.

An important feature of the book is the illustration of methods by the actual measurement of seven crystals of a triclinic substance. The readings of the goniometer scale are first given, and from these the reader is led through the entire series of processes: stereographic projection, assignment of indices, calculation of elements, and recalculation of angles, each given in its place as an example of the principles and formulæ employed. This practical illustration is a far more effectual means of recommending the methods to the reader than mere verbal description.

It will probably be found that these methods of calculation are the most valuable part of the book; they are so systematically arranged and tabulated that the various steps may be distinguished at a glance, and any numerical error must be detected at once, while much labour is saved by the methodical order in which the operations are conducted.

It is to be presumed that the laborious process of calculating the angle between each pair of faces from the elements by means of the general formula is given as an exercise in the method of least squares rather than as an example of the course to be actually adopted in any but rare cases.

One subject, however, of some importance is barely touched upon; namely, the criticism of images obtained from crystal faces on the goniometer, and their interpretation. Both in the descriptive paragraphs and in the above-mentioned illustration, all measurements of the same angle upon different crystals are assumed to be equally good, so that their arithmetic mean is adopted as the observed value, whereas the difficulties presented by multiple images seem to deserve treatment in a book which deals so exhaustively with the practical side of the subject. It is to be regretted also that the discussion of optical properties and measurement has been almost crowded out of the work.

H. A. M.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Remarkable Sunsets

SPEAKING of Virginia City, the great silver mining centre of Nevada State, I said, in "An Engineer's Holiday," that it "lies among the foothills of the Sierra, at an elevation of 6200 feet, on the eastern face of Mount Davidson . . . surrounded by innumerable interlocked mountains, conical in outline, red-brown in colour, and perfectly bare of all vegetation. These stretch, as far as the eye can reach, to where the snowy tops of the Humboldt peaks stand against the sky, and the terrible sterility of the scene is enhanced rather than relieved by the thin meanderings of the Carson River, whose course is marked by a narrow green line. This is the only sign of water visible in the arid panorama, whose bare, red cones are steeped all day in dust-haze, and lighted for a few minutes at sunset by an 'Alpenglow' which dyes the countless peaks in as countless gradations of rosy light."

It certainly did not occur to me, when I wrote the above three years ago, that the finer and higher particles of the dust-haze which obscures the dry air of the American desert may have been concerned in producing the splendid sunset effects which I witnessed at Virginia City; but this, after our recent experiences, seems very probable.

D. PIDGEON

Holmwood, Putney Hill, December 22

I HAVE received a letter, dated December 5, from Mr. Joseph Moore, of New Garden, North Carolina, U.S.A., in which he informs me that "the phenomena at both sunset and sunrise have been unusual in more than a dozen instances here during the autumn. Only the night before last we had an extraordinary sunset. The sky bore all the tints of which you speak, but I do not remember to have noticed the cirrus cloud in more than one instance. The sunsets have been subject for remark in quite a number of the papers." I inclose also a newspaper, the *Olive Branch*, of Hancock, Minnesota, U.S.A., which has been forwarded to me by another correspondent, containing a notice of the sunset of November 10.

[1] "Certain Dimensional Properties of Matter in the Gaseous State," *Phil. Trans.* 1879, Part II.

Richmond, Surrey, December 22 F. A. R. RUSSELL

IN a letter dated Tokio, October 3, describing a tour in the interior of Japan, Prof. James Main Dixon writes:—" During the two or three days at the end of August we enjoyed fine dry weather, but the sun was copper-coloured and had no brightness. It was capital weather for travelling, but rather inexplicable. When we got to Nikko, the people came to us to inquire if some catastrophe were impending, for the appearance of the sun foreboded evil. We laughed at their fears, and assured them all was right. However it seems that if the appearance of the sun foreboded no evil, it was a wonderful sign of the greatest earthquake and volcanic catastrophe on record. The fearful explosion of Krakatoa, in the Straits of Sunda, took place on August 26, and there seems little reason to doubt that the monsoon had carried the volcanic dust along with it, the dust obscuring the sun. The distance is nearly 3000 miles."

St. Andrews, December 22

Peripatus

DR. VON KENNEL, in a note on the "Development of Peripatus," which appeared in a recent number of the *Zoologischer Anzeiger*, and has been translated and printed in your columns, has thrown some doubt on the accuracy of the observations recorded in the late Prof. Balfour's memoir on the "Anatomy and Development of *Peripatus capensis* (*Quart. Journ. Micro. Sci.*, April, 1883). We trust that you will give us, as the editors of that memoir, this opportunity of making a few brief statements in reply to the somewhat unusually outspoken criticisms contained in his preliminary note.

Dr. von Kennel entirely omits to mention in his paper that Prof. Balfour's researches refer to a Cape species of Peripatus (*P. capensis*), whilst the species which he has worked at are West Indian, and differ considerably from *Peripatus capensis*.

Considering the fact, well known to embryologists, that there are numerous instances of great discrepancies in the embryonic history of closely-allied forms, it seems to us strange that the only explanation, suggested by Dr. von Kennel, of the differences between his results and those recorded in Prof. Balfour's memoir should be that the latter are absurdly erroneous.

The remarkable attitude which Dr. von Kennel has assumed in this matter must have been obvious to all competent zoologists. We offer these remarks mainly because his statements have appeared in a journal which has a wide circulation amongst readers who are not so well able to judge of the merits of the case.

We are able to state in conclusion that the results enumerated on pp. 256, 257 of Prof. Balfour's memoir have been confirmed by Mr. Sedgwick on a large number of fresh and well-preserved embryos of Peripatus from the Cape, obtained since the publication of the memoir.

H. N. MOSELEY
A. SEDGWICK

[THE translator of Dr. von Kennel's "Note on the Development of Peripatus," to whom we submitted the above letter, writes to us that, "though with a large experience in such matters, he is quite unable to see anything 'unusually outspoken' in Dr. von Kennel's criticisms; had any such occurred, he would have passed them over; nor does he find any foundation for the statement that Dr. von Kennel explains the results of Prof. Balfour's memoir as 'absurdly erroneous.' Dr. von Kennel, at the beginning of his note, only asserts that his observations *cast some doubt* on those of Balfour, apologetically adding that his material was immensely richer than Balfour's, and at the conclusion of his Note he simply calls attention to the discrepancies between his observations and Balfour's illustrations." At the translator's request we quote the original of the two critical paragraphs with the translations, so that the many competent zoologists who are amongst our readers can judge whether the latter adds to or takes from the spirit of the former.—ED. NATURE.

"Ich thue dieses hauptsächlich deswegen, weil die durch Moseley und Sedgwick publicirte Abhandlung aus dem Nachlass Balfour's einige Abbildungen von Embryonen und Schnitten durch solche enthält, deren Genauigkeit ich nach meinem reichlichen und ausgezeichnet conservirten Material und nach den Beobachtungen am frischen Objecte etwas anzweifeln muss, deren Deutung vollends die Probe nicht hält."

"I do this chiefly because the treatise published by Moseley and Sedgwick from the posthumous notes of Balfour contains some representations of embryos and cross-sections of the same, upon whose accuracy in details I, with my rich and well-preserved collection of specimens, and observations on fresh objects, must cast some doubt, and the interpretation of which does not bear investigation."

"Ich enthalte mich hier, um nicht weitläufig zu werden, jeder Discussion, muss jedoch noch einmal darauf hinweisen, wie wenig Balfour's Abbildungen und die Schilderungen der Herausgeber mit den hier mitgetheilten Thatsachen stimmen."

"I here abstain for the sake of brevity from all discussion, but must, however, call attention to the fact how little Balfour's illustrations and the descriptions of the Editors agree with the facts as they are here given."]

A New Rock

DURING my visit last summer to Lake Sagvand, in the Balsfjord, near the city of Tromso, I discovered a new enstatite-bearing rock, which forms entire little hills. It is composed of light yellow-green enstatite, mixed with magnesite. The magnesite, which is entirely free from lime, is partly white, partly dirty grey in colour, in which latter state it contains a little oxidulated iron, and appears then distinctly crystalline, with rhomboidal planes of cleavage. The rock is greatly interspersed with little grains of chromite, which are found in the enstatite as well as the magnesite. Here and there small grains of pyrite also appear. The substance is perfectly free from olivine, at all events neither olivine nor serpentine has been discovered under microscopical analysis.

The rock must be considered a new petrographical species. I have named it "Sagvandite," from the place where it was first discovered. It appears with a strong reddish-brown colour on its uneven surface, where the magnesite is completely washed out, so that the enstatite alone remains. The rock is not slaty, and must so far be said to be of massive structure.

When I have had an opportunity of thoroughly analysing the new substance, I propose to give a complete description of it in NATURE. KARL PETTERSEN

Tromso Museum, Finmarken, Norway, December

Diffusion of Scientific Memoirs

IN his notice of the Reprint of Prof. Stokes' papers in NATURE for Dec. 13 (p. 145), Prof. Tait, with characteristic incisiveness, speaks of the "almost inaccessible" volumes of the *Cambridge Philosophical Transactions*, and proceeds to offer an "easy cure" for that simple though grave malady. I think if Prof. Tait had taken the trouble to make the inquiry he would have found that very few societies are so liberal in the free dissemination of their publications, and that the number of universities, prominent societies, or libraries which do not receive them gratis, or merely in exchange, is very small.

December 14 W. M. HICKS

THE question so pointedly at issue between Mr. Hicks and myself is one which can be settled by statistics only. NATURE would do a real service to science by collecting statistics as to the *numbers* of different centres (home, and foreign, separately) at which the *Transactions* of various scientific Societies were freely accessible in 1883 (say); and also the corresponding numbers in 1853. The Royal Society regularly publishes such information in its *Transactions*, so does the Royal Society of Edinburgh.

I have been a Fellow of the Cambridge Philosophical Society for about 30 years; and, during that time, I have received from the Society some fasciculi (of *Proceedings* only) certainly not amounting to a dozen in all:—and I am not aware that my case is an exceptional one.

Mr. Hicks writes as if he thought I was bringing an accusation. Surely the figure, of *malady*, which I was careful to employ, cannot be so construed. P. G. TAIT

THE "TALISMAN" EXPEDITION[1]

AT the public meeting of the five Academies on October 29, 1882, I had the honour of reporting on the explorations of the *Travailleur*, and I announced that this year a new scientific campaign would be undertaken in the Atlantic. The Minister of Marine, responding to the desire expressed by his colleague, the Minister of Public Instruction, and by the Academy, had, in fact, issued the necessary orders to have the *Talisman* equipped for this purpose. The *Talisman* is an excellent screw steamer, provided with a good spread of canvas, sufficient to make good way without the aid of its engines. For several months it was placed in dock at the Rochefort Arsenal, where the naval engineers undertook to refit it for the service to which it had been appointed. The old hempen ropes intended for raising the dredges were replaced by a steel cable of great strength and flexibility, capable of a strain of about 4500 kilogrammes, and worked by two steam-engines. One of these set in motion the enormous bobbin on which the cable was wound. The other, a still more powerful engine, was intended for raising the dredges.

Large bag-nets, or trawls, with an opening of two or three yards, advantageously replaced the heavy drags we had formerly used. The soundings were executed by means of an apparatus perfected by M. Thibaudier, naval engineer, and so disposed as to prevent the motions of the vessel from in any way affecting the tension of the steel cable, which was arrested by an automatic break as soon as the sounder touched the bottom.

In order to gauge the temperature at great depths I had an apparatus constructed by which a mercurial thermometer (Negretti and Zambra) could be turned over at any moment. At the same time the capillary extremity of a glass tube, where a vacuum had been made, and into which the sea water then rushed, broke, supplying perfectly pure specimens, capable of being preserved for any length of time by soldering the tubes. Our friend, Colonel Perrier, had kindly lent me a Gramme machine, which generated the electricity for some Edison lamps, so disposed as to light up our apparatus, or, when needed, to penetrate to depths not exceeding 35 metres. At my request the command of the *Talisman* had been intrusted to M. Parfait, frigate captain, who had held the same position the year before on board the *Travailleur*.[2] I may here be permitted to express to the officers of the *Talisman* the feelings of gratitude inspired in us by their devotion. They cooperated with us with unflagging zeal, and for whatever success attended our mission we are indebted to them.

On May 30, the scientific mission[3] met at Rochefort, and on June 1 the *Talisman* set sail. The voyage of 1883 may be divided into several distinct stages. Our object was to study the coast of Africa as far as Senegal, then the waters of the Cape Verde, Canary, and Azores Archipelagos, volcanic lands which could not fail to supply us with interesting materials. Lastly, we hoped to be able to devote our attention to the Sargassum Sea, its fauna, and the nature of its bed.

The sea bed stretching westward of Morocco and the Sahara is extremely uniform, no longer presenting those rugged reliefs that had so impeded our operations on the coast of Spain. On the contrary, the slope is here so gentle that at greater or less distances from the land it was always possible almost infallibly to light upon the needed depths. In these waters we made about 120 dredgings, and in a few days we had determined the bathymetric distribution of the local fauna with sufficient accuracy to enable us to indicate the levels explored from the contents of our nets.

At 500 or 600 metres live numerous fishes, such as Macrurus, Malacocephalus, Hoplostethus, Pleuronectes, as well as prawns of the genus Pandalus, belonging to a new species with a rostrum pointed like a sword; some Peneæ, Pasiphaæ, a few small crabs (Oxyrhynchidæ, Portunidæ, Ebalidæ), pink Holothurians, some rare specimens of Calveria, that soft Echinoderm discovered in our waters by the naturalists of the *Porcupine*, and previously known in the fossil state; several very large sponges, such as Askonema and Farrea.

At greater depths, from 1000 to 1900 metres, fishes still abound,[1] and often formed the bulk of our captures. They were generally of a dull colour, with gelatinous flesh, and their skin covered with a thick mucous coating. Several had phosphorescent spots, serving to give them light in the dark regions they inhabit. Here Pandali give place to the new genus Heterocarpus, and to gigantic blood-red prawns with enormously long antennæ, which were new to science and may be placed in the genus Aristeus. The Nephropsis make their appearance at this level. They are blind, coral-tinted Crustaceæ, who seem to be distributed over a wide geographical range, for they have been found on the other side of the Atlantic in the Caribbean Sea, and a closely allied species has been fished up at a great depth near the Andaman Islands. The blind Polycheles, which in the present epoch represent the Jurassic Eryons, burrow in the mud, leaving nothing visible except their long hooked nippers, adapted for seizing the passing prey. Some crabs are still found, such as Maiadæ (Scyramathia, Lispognathus), a new species of Homolia, and Lithodes, hitherto supposed to be peculiar to Arctic and Antarctic seas. Lastly, numerous forms were also observed of the genus Galathea, several of which have their eyes transformed to spines. Sponges are extremely common, most of them with siliceous skeletons. We brought up great numbers of Rosella, Holtenia of several species, the rock crystal-like beards white as snow were buried in the mud, the sponge mass alone emerging; some Aphrocallistes, with solid skeletons of the most elegant form. Calveria became more numerous; Holothurians of the genus Loetmogone, and other species of the same family, crawled on the bottom in the midst of Asteria, Ophiuria, and Brisinga. The nets often returned filled with so much treasure that they could not all be classed within the day.

While rounding Cape Ghir and Cape Nun, some 120 miles from the coast, the *Talisman* spent several days in exploring a very regular bank at a depth of about 2000 to 2200 metres. It was on this ground that on Aug. 2, 1882, the *Travailleur* had captured the curious fish described by M. Vaillant under the name of *Eurypharynx pelecanoides*, and two specimens of which were taken this year.

Our prizes were again of great value. Magnificent sponges, allied to those that have been described under the name of *Euplectella suberea* were here found mingled with large violet Holothurians of the genus Benthodytes, and with other species of the same genus, remarkable for their dorsal appendices. A Calveria, distinct from those found at lesser depths, some Brisingæ, Polyps of rare beauty (Flabellum, Stephanotrochus), a Democrinus and a Bathycrinus, not yet described, very numerous Crustaceæ, nearly all new to us and belonging to the group of the Galatheæ (Galathodes, Galacantha, Elasmonotus), completed the list of invertebrates. The fishes were very varied, and their study will furnish new facts of the greatest interest to science. Amongst the most remarkable I may mention *Melanocetus johnsoni*, Bathytrochtes, a Stomias with phosphorescent spots, and several Malacostei.

---

[1] Preliminary Report on the *Talisman* Expedition to the Atlantic Ocean. By M. Alphonse Milne-Edwards, President of the Submarine Dredging Commission. Communicated by the author.

[2] The staff consisted of M. Antoine and M. Jacquet, lieutenant, of MM. Gibory and Bourget, midshipmen, of M. Vincent, doctor of the first class, of M. Huas, assistant doctor, and of M. de Plas, chief mate.

[3] The mission consisted of M. A. Milne-Edwards, Member of the Institute, President, of M. de Folin, MM. Vaillant and Perrier, professors in the Museum, MM. Marion and Filhol, professors in the Faculty, M. Fischer, assistant naturalist in the Museum, MM. Ch. Brongniart and Poirault, added as assistants.

[1] To Macrurus are here added the following genera: Bathynectes, Coryphenoides, Malacocephalus, Bathygadus, Argyropelecus, Chauliodus, Bathypterois, Stomias, Malacosteus, Alepocephalus.

Between Senegal and the Cape Verde Islands our trawls reached depths varying from 3200 to 3699 metres, and brought up most of the preceding species besides many others (Crustaceans, Mollusks, Zoophytes, Sponges) which had never elsewhere been met.

These last takes brought to a close the first part of our programme, and on July 20, after ninety-one days of navigation, we cast anchor in the Bay of La Praia, at Santiago in the Cape Verde Archipelago. This volcanic group detained us a few days, and while zoological, botanical, and geological excursions were being made ashore, the *Talisman* was searching the irregular beds on the coasts for marine animals, and especially for the red coral, which for some years back has formed the object of an active trade in these islands. I will not dwell on these in-shore explorations, nor on those of the islet Blanco, where we were able to study on the spot the large Saurians (*Macroscincus coctei*) which seem limited to this isolated rock.

All these details are recorded in the report which I have addressed to the Minister and which will soon be published.

In the deep waters of the Cape Verde Archipelago life displays a surprising energy. Our nets came up overflowing with specimens after a single plunge. We captured at one take more than 1000 fishes belonging mostly to the genus Melanocephalus, about 1000 Pandali, 500 prawns of a new species of the genus Nematocarcinus, with disproportionately long claws, as well as many other species.

On the evening of July 30 the *Talisman* took a north-westerly course in the direction of the Sargassum Sea. I need not enter into details on this part of our journey, and it will suffice to say that we nowhere met those dense floating masses of vegetation mentioned by the old navigators. The Gulf weed was seen in isolated patches drifting either with the marine or atmospheric currents, and harbouring a whole pelasgic population, whose colours harmonised admirably with those of the algæ that afforded them a refuge. Our naturalists made a careful study of these forms.

The soundings of the *Talisman* in this region show in a general way that, starting from the Cape Verde Islands, the marine bed falls regularly as far as about the 25th parallel, where it attains a depth of 6267 metres. Then it gradually rises towards the Azores and the 35th parallel, where it is about 3000 metres. These results are far from agreeing with the curves indicated on the most recent bathymetric charts. The bed of the Sargassum Sea seems formed of a thick layer of a very fine mud of a pumice nature, covering fragments of pumice and volcanic rocks. Here there would appear to stretch, at over three miles from the surface of the ocean, a vast volcanic chain parallel with the African seashore, and of which the Cape Verde Islands, the Canaries, Madeira, and the Azores are the only parts not submerged. The submarine fauna is poor, consisting of few fishes, some Crustaceans, such as Paguri, which lodge in colonies of Epizoanthus, prawns of the genus Nematocarcinus, Pasiphaæ, a few mollusks (Fusus, Pleurotoma, and Leda), which scarcely sufficed to repay the time required for such deep dredgings. Not that our captures did not again become abundant towards the northern limit of the Sargasse Sea, when the depths shrank to 3000, 2000, and 1500 metres. It was here that we took the giant of the family of the Schizopodes, a Gnathophausia of a blood-red colour measuring nearly 25 centimetres in length.[1]

A short delay at Fayal, and again at San Miguel in the Azores, enabled us to compare the volcanic phenomena still active at certain points with those we had studied on the summit of the Peak of Teneriffe. The analogy is very striking between the rocks, the gaseous products, and the sulphur deposits of the two islands. From what is now taking place on the surface of the ground, an idea may be formed of the submarine convulsions which have covered the bed of the Sargassum Sea with pumice and igneous rocks.

The return voyage from the Azores to France was effected under the most favourable conditions, and we were able to make daily dredgings in depths of from 4000 to 5000 metres. These difficult operations, very skilfully carried out by Captain Parfait, brought us an extremely valuable harvest. Under this tremendous pressure, in perfect darkness, and without a trace of vegetation, animal life is still vigorous. Large fishes of the genus Macrurus, as well as some Scopeli and Melanoceti seem to be here far from rare. Some Pagures and Galatheæ of new form, a gigantic Nymphon of the genus Colossendeis, some unknown Ethusæ, besides Amphipods and Cirrhipeds represent the Crustacean group. But this abyssal fauna owes its peculiar physiognomy to the number, variety, and size of the Holothurians.

The marine bed is carpeted throughout this region with a thick white mud, composed almost exclusively of Globigerini, and covering pumice deposits and fragments of various kinds of rocks. Some of these rocks brought up in our nets bore the impress of fossils, amongst others of Trilobites. But what still more surprised us was to find at a distance of over 700 miles from the European coast pebbles polished and striated by the action of ice. The sharpness of the striæ excludes the supposition of transport by the currents. The presence of these pebbles is probably due to the action of the icebergs, which in the Quaternary epoch advanced further southwards than at present, and which, by melting in the region of the Atlantic comprised between the Azores and France, deposited on the bottom of the sea the stones carried off from the glacier beds and conveyed to this distance from Europe.

On August 30 we dredged for the last time on the steep slope by which the oceanic depths are connected with the Bay of Biscay, and our captures added to the fauna of the French waters a large number of new or interesting species.

It was high time to return to Rochefort. Our casks and cases were full, our alcohol exhausted. This voyage has furnished us with unrivalled materials for study, materials which must now be put in order. The Minister of Public Instruction has recognised their importance, and has supplied me with the means of beginning the publication of the results. It is my intention to place before the public the collections that have been made during the explorations of the *Travailleur* and *Talisman*. These treasures will be exposed in a special exhibition, which will be held in one of the halls of the museum towards the beginning of January.

---

[1] *Gnathophausia goliath*, new species.

MUSIC AND SCIENCE[1]

It would seem that Science, like History, may at times repeat itself: for in this bright little pamphlet we have a revival of the Old World controversy, which dates from the days of Pythagoras, Plato, Aristotle, and Euclid. The author takes, however, for its text, a somewhat declamatory and *ad captandum* modern passage from the *Revue de Paris*, which declares, with an emotional warmth totally uncalled for under the circumstances, that harmony is not a science, and that music is an art, "but a divine art." To appreciate thoroughly the question in debate it is necessary to go back to the sense of the original Greek words—*ἁρμονία* and *μουσίκη*. The former means "mathematical agreement"; the second "artistic culture." It is with their "second intentions," or acquired and more limited meanings, that we now have to deal. Is music, in the English sense of the word, which no wise differs from the Italian, an art or a science? It is clearly both; but the art, *μουσίκη*, so far predominates in public acceptance and cultivation over the science, *ἁρμονία*, that the latter is, and has been for many centuries, in danger of succumbing altogether. Indeed, though excellently begun by Euclid in his "Sectio Canonis," it remained all but unadvanced until the recent researches of Helmholtz. It is to Aristotle that we owe the general test by which to distinguish an art from a science; a test so satisfactory and so neat, that it produces the effect on the mind of a mathematical demonstration; a form of proof which is too often only a roundabout way of restating a self-evident proposition. Aristotle said that art at its best only works by "rule of thumb"; and states that *τέχνη* is governed by rules. When these rules are found to rest on recognised laws, the art becomes an *ἐπιστήμη*, or science. This observation, made two thousand years ago by the shrewdest of all shrewd observers, remains as true and as fresh as on the day when it was promulgated. To no branch of human learning does it apply with such force and directness as to music. For perfection in this art has always been, is now, and must continue to be, confined to a few sensitive, delicate, finely-strung natures, which differ from those of their fellow-creatures in possessing a peculiar technical power and organisation such that they instinctively reproduce, and as it were consonate to the musical conceptions of other minds. In all other respects they may be self-indulgent, unbusinesslike, unpractical; even, as indeed not uncommonly they are, over-sensitive and disagreeable. Types of this class are Beethoven, Cherubini, Mozart, Weber, and Berlioz. In them, in fact, the full development of artistic perfection has eaten up all other good qualities, and left no time or inclination for what Plato calls "the practice of virtue." The world at large, secretly conscious of its special inferiority, and always willing to discharge itself of an unwelcome responsibility, too commonly looks upon these exceptional natures as representing the whole, and not only the artistic and executive side of music. But the other exists notwithstanding; and its fuller cultivation will tend much to restore the balance so disturbed. In this respect the little book of Dottore Crotti has special value. It deals with the foundation of rhythm and of music, and with the strange and hitherto unexplained emotional difference between the major and minor scales, which in the Italian are prettily and correctly named *Gaia* and *Triste* respectively. The ratios of musical intervals and their combination are fully treated, and with some features of novelty, especially as concerns their physiological effects on the ear. The great fact, so much forgotten in this century since the brilliant jigs of the Rossinian school have become popular, that it is the bass, and not the treble or melody, which is fixed and fundamental, is stated with abundant emphasis, and distinction is made between the characters of repose and of movement in different kinds of music. The assumption that the scale is founded principally on the fractions representing the major and minor tones with only a simple semitone of $\frac{16}{15}$ seems hardly sufficient to meet theoretical requirements; but otherwise there is much of interest comprised within the 55 pages of which the pamphlet consists. It has the merit, moreover, beyond the historical point already noted, of bearing out its title of "acoustico-physiological," and of adverting to the mental or receptive side of musical impressions more than occurs in some modern treatises.

W. H. STONE

THE REMARKABLE SUNSETS

THE following letter has been sent to Mr. Norman Lockyer:—

The remarkable sunsets which have been recently witnessed upon several occasions have brought to my recollection the still more remarkable effects which I witnessed in 1880 in South America, during an eruption of Cotopaxi; and a perusal of your highly-interesting letter in the *Times* of the 8th inst. has caused me to turn to my notes, with the result of finding that in several points they appear to have some bearing upon the matter which you have brought before the public.

On July 3, 1880, I was engaged in an ascent of Chimborazo, and was encamped on its western side, at 15,800 feet above the sea. The morning was fine, and all the surrounding country was free from mist. Before sunrise, we saw to our north the great peak of Illiniza, and twenty miles to its east the greater cone of Cotopaxi, both without a cloud around them, and the latter without any smoke issuing from its crater—a most unusual circumstance; indeed, this was the only occasion on which we noticed the crater free from smoke during the whole of our stay in Ecuador. Cotopaxi, it should be said, lies about forty-five miles south of the equator, and was distant from us sixty-five miles.

We had left our camp, and had proceeded several hundred feet upwards, being then more than 16,000 feet above the sea, when we observed the commencement of an eruption of Cotopaxi. At 5.45 a.m. a column of smoke of inky blackness began to rise from the crater. It went up straight in the air, rapidly curling, with prodigious velocity, and in less than a minute had risen 20,000 feet above the rim of the crater. I had ascended Cotopaxi some months earlier, and had found that its height was 19,600 feet. We knew that we saw from our station the upper 10,000 feet of the volcano, and I estimated the height of the column of smoke at double the height of the portion seen of the mountain. The top of the column was therefore nearly 40,000 feet above the sea. At that elevation it encountered a powerful wind blowing from the east, and was rapidly borne for twenty miles towards the Pacific, seeming to spread very slightly and remaining of inky blackness, presenting the appearance of a gigantic inverted └, drawn upon an otherwise perfectly clear sky. It was then caught by a wind blowing from the north, and was borne towards us, and appeared to spread rapidly in all directions. As this cloud came nearer and nearer so of course it seemed to rise higher and higher in the sky, although it was actually descending. Several hours passed before the ash commenced to intervene between the sun and ourselves, and when it did so we witnessed effects which simply amazed us. We saw a green sun, and such a green as we have never, either before or since, seen in the heavens. We saw patches or smears of something like verdigris-green in the sky, and they changed to equally extreme blood-reds, or to coarse brick-dust reds, and they in an instant passed to the colour of tarnished copper or shining brass. Had we not known that these effects were due to the passage of the ash, we might well have been filled with dread instead of amazement; for no words can convey the faintest idea of the impressive appearance of these strange colours in the sky, seen one minute and gone the next, resembling nothing to which they can be properly compared, and surpassing in vivid intensity the wildest effects of the most gorgeous sunsets.

The ash commenced to pass overhead at about midday. It had travelled (including its detour to the west) eighty-five miles in a little more than six hours. At 1.30 it commenced to fall on the summit of Chimborazo, and before we began to descend it caused the snowy summit to look like a ploughed field. The ash was extraordinarily fine, as you will perceive by the sample I send you. It filled our eyes and nostrils; rendered eating and drinking impossible; and reduced us to breathing through handkerchiefs. It penetrated everywhere, got into the working parts of instruments, and into locked boxes. The barometer employed on the summit was coated with it, and so remains until this day.

That which passed beyond us must have been finer still. It travelled far to our south, and also fell heavily upon ships on the Pacific. I find that the finer particles do not weigh the 1/25,000 part of a grain, and the finest atoms are lighter still. By the time we returned to our encampment the grosser particles had fallen below our level, and were settling down into the valley of the Chimbo, the bottom of which was 7,000 feet beneath us, causing it to appear as if filled with thick smoke. The finer ones were still floating in the air, like a light fog, and so continued until night closed in.

In conclusion, I would say that the terms which I have employed to designate the colours which were seen are both inadequate and inexact. The most striking features of the colours which were displayed were their extraordinary strength, their extreme coarseness, and their dissimilarity from any tints or tones ever seen in the sky, even during sunrises and sunsets of exceptional brilliancy. They were unlike colours for which there are recognised terms. They commenced to be seen when the ash began to pass between the sun and ourselves, and were not seen previously. The changes from one hue to another, to which I have alluded, had obvious connection with the varying densities of the clouds of ash that passed; which, when they approached us, spread irregularly, and were sometimes thick and sometimes light. No colours were seen after the clouds of ash passed overhead and surrounded us on all sides.

I photographed my party on the summit of Chimborazo whilst the ash was commencing to fall, blackening the snow furrows; and, although the negative is as bad as might be expected, it forms an interesting souvenir of a remarkable occasion. EDWARD WHYMPER

December 21

NOTES

THE announcement that Prof. Flower has accepted the appointment of superintendent at the Natural History Museum, vacated by the resignation of Prof. Owen, is premature, though we believe that steps are being taken to secure Prof. Flower's services for that important appointment.

WE regret to have to record the death of M. Yvon Villarceau, one of the astronomers of the Paris Observatory and a member of the Academy of Sciences for more than twenty years. M. Yvon Villarceau had been a pupil of the École Central des Arts et Manufactures, and was regarded as one of the most eminent of French mathematicians.

IT has been arranged by H.M. Trawling Commissioners that Prof. McIntosh, of the University of St. Andrews, will proceed systematically at intervals (probably once a fortnight) to the trawling grounds on the east coast of Scotland for the next six months, and undertake certain investigations concerning the grounds and their inhabitants. Each trip will probably occupy about two days. The Granton General Steam-Fishing Company's steam-trawler *Wallace*, which is fitted with all the recent appliances for such work, and is a swift and powerful steamer, will be used for the investigations, which will be at once commenced. An experienced long-line fisherman and trawler from St. Andrews (Alex. W. Brown) will accompany the professor as assistant.

THE friends of the late Mr. W. A. Forbes, the Prosector of the Zoological Society of London, have decided to collect his most important papers in a memorial volume, and the following gentlemen have been appointed to act as a committee for this purpose:—Prof. Flower, Prof. Bell, Mr. H. H. Johnston, Mr. Mivart, and Mr. Sclater. The committee find that Mr. Forbes's papers can be most suitably republished in a form similar to that adopted in the memorial volume of the memoirs and papers of Mr. Forbes's predecessor in the Prosectorial office (the late Prof. Garrod). Following the precedent of the "Garrod Memorial Committee," they propose to ask for subscriptions of one or more guineas, and to give to subscribers a copy of the work for every guinea subscribed. Mr. Sclater will edit the Forbes Memorial Volume, Mr. Johnston will prepare a biographical notice and portrait, and Mr. F. Jeffrey Bell, 5, Radnor Place, Gloucester Square, W., will act as Secretary and Treasurer.

THE appointment of a Japanese student as assistant to the Professor of Anatomy at Berlin has been approved by the Minister of Public Worship.

MR. FRANCIS ELGAR, Consulting Naval Architect and Engineer in London, has been unanimously elected by the Glasgow University Court to the John Elder Chair of Naval Architecture.

AN expedition is at last being organised under the auspices of the British Association to proceed to Mount Kilimanjaro, the snow-clad peak of Eastern Equatorial Africa. The party will be under the charge of Mr. H. H. Johnston, who has recently returned from the Congo. The party will leave England at the beginning of March.

HEAVY indeed is the burden of educating laid upon the Southern States! With only one half at school of a population the illiterate proportion of which, among both whites and negroes, is increasing, and in some States this increase of illiteracy greater among the whites than among the negroes; with the negro, the non-taxpaying element, increasing fastest, notwithstanding white immigration; with trades destroyed, and property in consequence reduced in value 40 per cent., and in some States still falling in value; with the franchise, nevertheless, given to this increasing body of ignorance; evil indeed may be the result to a republic if the whole Union does not assist to correct it. Emancipation was a national act, and the nation ought to meet the inevitable consequence. So urges Dr. Haygood, in the United States educational circulars referred to last week, with the warning that no white men will agree for long to be voted down by a majority of illiterate blacks and whites.

ON Thursday, at 9.21 p.m., a shock of earthquake was felt in Fünfkirchen, a town in the south of Hungary, not far from the confluence of the Danube and Drave. The shock lasted two seconds, and was accompanied by a loud underground rolling noise. At the same time a similar earthquake and noise occurred at Barcs, a place to the south-east of the former, on the banks of the River Drave. Both shocks moved northwards. An earthquake shock was also felt at Lisbon at 1.30 a.m. on the 22nd inst., but did not excite much notice. A second shock, which lasted twelve seconds, occurred two hours later; being accompanied by subterranean rumblings, it awoke the entire population, and caused a panic among the inhabitants in the narrow streets. The seismic wave passed from northwest to south-east.

THE fourteenth Annual Report of the Botanic Garden Board of New Zealand (1883) contains valuable information as to the ravages of certain scale insects (*Coccidæ*) in the colony. They appear to be principally of two kinds: one is an *Icerya*, nearly related to the sugar-cane pest of Mauritius, &c., the other a *Mytilaspis* allied to the common "apple scale" (*M. pomorum*). The *Icerya* is called the "wattle blight," but appears by no means to confine its ravages to the wattle trees. According to Mr. Maskell, it is the *Mytilaspis* that is the more serious, for it overruns in countless millions all kinds of fruit and other trees (fortunately it appears to be enormously infested and destroyed by a parasite). With regard to remedies, there is a little vagueness in the Report, owing apparently to the confusion of the two insects. The first portion speaks only of the *Icerya*, and states that Mr. Engle of Nelson had completely destroyed it by the application of kerosene and fish oil. Subsequently Mr. Maskell, dealing with the *two* species, says that a mixture of kerosene and linseed oil (one-third or one-fourth of the former) as recommended by Mr. Comstock in America, had been perfectly successful so far as regards the *Mytilaspis*, which he does not regard as serious in its probable effect upon wattles (*Acacia*), but very serious with respect to fruit and other trees. On the other hand, he considers all remedies useless against the *Icerya* of the wattle other than the radical one of cutting down and destroying the affected trees. No indication is given, however, of the use of a force-pump in distributing the kerosene; if this were used, the remedial agent might be distributed to a greater height than would be possible by mere hand application, and moreover it might be made to penetrate dense hedges, &c., the interior of which it would be impossible to drench by hand labour. The improved form of application, as a "kerosene emulsion," recommended by Prof. Riley and Mr. Hubbard, did not appear to be known in New Zealand at the time the Report was drawn up. Any way it is satisfactory to hear that the *judicious* application of kerosene will certainly destroy scale insects without necessarily damaging the plants.

THE same Report speaks very hopefully of the ultimate success of attempts to cultivate hops in the province of Wellington; in Nelson success has been already secured. The great drawback is the expense of providing the necessary *poles*, and much stress is laid upon the necessity for cultivating oak, ash, birch, and species of *Eucalyptus* for that purpose. Of the indigenous poles, those of *Myrsine urvillei* are said to be the most durable.

THE additions to the Zoological Society's Gardens during the past week include a Toque Monkey (*Macacus pileatus* ♀) from Ceylon, presented by Mr. J. H. Barker; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. Douglas; a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Mrs. Archer; a Moorhen (*Gallinula chloropus*), British, presented by Mr. T. E. Gunn; a Gannet (*Sula bassana*), British, presented by Mr. J. C. Baxter; two St. Thomas's Conures (*Conurus xantholæmas*) from St. Thomas, West Indies, presented by Mr. C. Wallis Enslie; two Fringed-lipped Lampreys (*Petromyzon branchialis*), British, presented by the Rev. F. T. Wethered; a Pied Wagtail (*Motacilla lugubris*), British; a Slaty Egret (*Ardea gularis*), European, purchased.

INTERNATIONAL POLAR OBSERVATORIES

I BEG to inclose you an extract from a letter just received from Prof. Wild, President of the International Polar Committee, and which gives information as to the several expeditions which conducted observations in the circumpolar regions during the twelve months ending August 31, 1883.

ROBERT H. SCOTT

"I take this opportunity of stating concisely what I have hitherto learnt as to the present condition or the return of the various expeditions.

"1. The United States—Point Barrow.—The Expedition was to have returned in the summer of 1883. Definite information as to its return has not yet been received.[1]

"2. England and Canada—Fort Rae, on the Great Slave Lake.—According to a communication received from Mr. Scott, dated November 21 last, the Expedition has safely returned to England.

"3. United States—Lady Franklin Bay.—The attempts to relieve the Expedition this summer by ship have, like those of last year, failed owing to the unfavourable condition of the ice. (Extract from newspapers.)

"4. Denmark—Godhavn, in Greenland.—According to a communication from Captain Hoffmeyer, dated December 8, the Expedition has safely returned to Copenhagen with a rich store of observations.

"5. Germany—Cumberland Sound (Davis Strait).—According to a communication received from Dr. Neumayer, dated November 1, the Expedition has safely returned to Hamburg, having completed its task in a satisfactory manner.

"6. Count Wilczek's Station (Austria)—Jan Mayen, in Mary-muss Bay.—The Expedition has safely returned to Vienna, having completely carried out its programme. A short report of its operations has been published by M. von Wohlgemuth, the Chief of the Expedition.

"7. Sweden—Spitzbergen (Cape Thordsen, in the Ice Fjord).—Dr. Rubenson states that the Expedition has safely returned to Stockholm.

"8. Norway—Bossekop, near Alten.—From a letter from Prof. Mohn, dated September 7, the Expedition stopped work on August 31, having completely carried out its programme, and on September 17, according to a report in *Naturen* (October, 1883) it safely returned to Christiania.

"9. Finland—Sodankyla.—The Expedition completed its task for the first year, but, according to a communication from Prof. Lemström, dated August 5, the observations will be continued another year, as the Government of Finland has provided the funds for the purpose.

"10. Russia—Nova Zembla (Möller Bay).—The Expedition returned to St. Petersburg in October with a rich store of observations.

"11. Holland—The Kara Sea.—The Expedition could not reach its original place of destination, Port Dickson, but was surrounded by ice in the Kara Sea, and has, according to a letter from Prof. Buys Ballot, dated October 1, safely returned to Utrecht, having under the circumstances only imperfectly carried out its programme.

"12. Russia—Mouth of the Lena (Sagastyr).—The Expedition, which suffered from storms during the passage down the Lena, was not properly established until October 20, 1882; from that date it has been able to carry out all the work laid down in the programme. It will continue its observations for another winter.

"13. France—Cape Horn (Orange Bay, Terra del Fuego).—According to a report from Prof. Mascart, dated November 17, the Expedition has returned safely to Paris, with a rich store of materials.

"14. Germany—The Island of South Georgia (Moltke Harbour).—This Expedition has also safely returned, according to a communication from Dr. Neumayer.

"Of the fourteen Expeditions, therefore, three will continue their observations for about another year (Lady Franklin Bay, Sodankyla, and Lena delta); the continuance of a fourth (Point Barrow) is at present unknown, the other ten have safely returned."

---

[1] We believe this party arrived at San Francisco some weeks ago.—ED.

MOVEMENTS OF THE EARTH[1]

III.—*Rotation of the Earth*

THE several ideas concerning the movements of the earth which were introduced in the last lecture will in the present one have to be dealt with in greater detail.

It was then agreed that if the whole expanse of the heavens were to travel with a perfectly equable motion in one direction, such a motion for instance as would result from all the stars being fixed to a solid transparent substance like those crystal spheres that the ancients really believed to exist; or if, on the other hand, the earth herself, instead of being free to turn as she listed with varying velocity in any direction, really went with perfect constancy in the direction opposite to the apparent motion of the stars, the visible effects would be the same in both cases, so that an appeal to our eyes would not suffice to enable us to say whether the earth moved or whether she remained at rest while the celestial sphere revolved around her.

Under these circumstances what is to be done? It has been seen how, both with regard to the measurement of space and the measurement of time for astronomical purposes, those interested in the physics and beauties of the various classes of celestial bodies outside our own earth have picked and chosen now one bit of physical science and now another to help them in their inquiries; and with regard to this very important question, "Does the earth move or is she at rest?" we shall see how very beautifully and perfectly the question has been answered by the application of certain mechanical principles.

The majority of people, I suppose, have some acquaintance, however slight, with machinery—with steam engines for instance; and it is a familiar fact how very important a part is played in the steam-engine by the flywheel. Why should that be? Why should this flywheel be so important that it is only quite recently that mechanicians have learned to do without it? For this reason: if a mass of matter such as a flywheel is once made to revolve, it will retain that motion for a long time, resisting any tendency to an increase or decrease of its velocity. It is in consequence of this property which the revolving flywheel possesses that an engineer is able to get over the dead points in his engine, whilst it also acts in preventing the engine making too sudden a start. In addition to this, when we have a mass of matter in the condition of the revolving flywheel it has some very peculiar qualities, only observed when such a mass of matter is in motion. If, then, we have a wheel so arranged that a very rapid rotation is being imparted to it, it does not behave as it would when at rest. These properties possessed by a rotating body can be well shown by an instrument known as the gyroscope, of which we shall speak more fully later on. It consists essentially of a disk to which a very rapid rotation can be imparted by a train of wheels or by other means. If the disk be set rotating, it is found to possess those curious qualities of which I have spoken. If whilst rotating at a high velocity it be placed in the position shown in Fig. 27, it will not fall, but will take on a movement of revolution round the stand.

---

[1] Continued from p. 69.

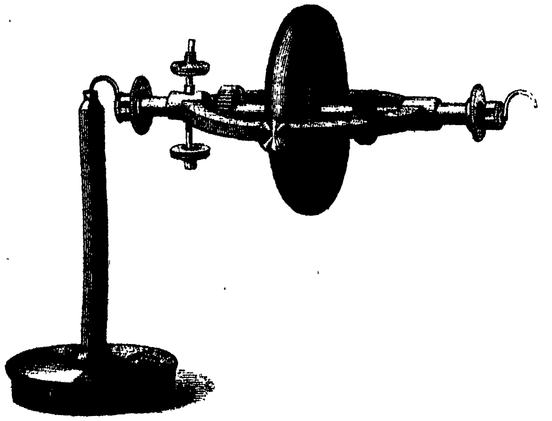

FIG. 27.—Rapidly rotating wheel supported at one end of its axis.

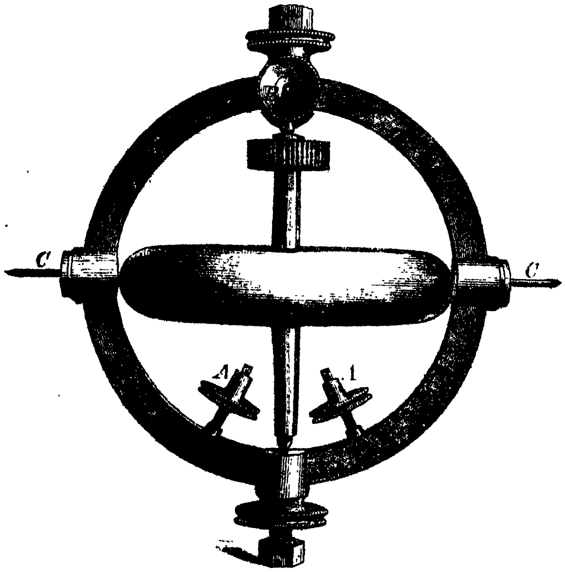

FIG. 28.—Rotating disk of gyroscope. C C, knife edges; A A, B B, adjusting weights.

From considerations suggested by this and other similar experiments, Foucault pointed out that it might be demonstrated whether the earth moved or whether she remained at rest. It struck him that the problem should be attacked somewhat in this manner:—

Suppose the earth to be at rest, and that either at the north or south pole a pendulum, suspended so that its point of support had as little connection with the earth as possible—so that it should, in fact, like the rotating flywheel, be independent of external influences, were set vibrating. Then an observer at the north or south pole would note that the swinging pendulum (the earth being considered as at rest) always had the same relation to the objects on his horizon. But, said Foucault, suppose that the earth does move. Then the swing of such a pendulum would not always be the same with regard to the places on the observer's horizon. Let the earth be represented by a globe. Suppose it to rotate from west to east. Place it with the north pole uppermost, and set the pendulum, whose point of support is disconnected from the rotating earth, vibrating. Then the pendulum will appear to travel from left to right as the earth rotates from right to left beneath it. Now suppose the pendulum to be suspended in the same way at the south pole, right and left now being changed. The earth of course rotates in the same direction as before, but the pendulum now appears to change the plane of its swing from right to left. At the equator the earth simply rotates straight up and straight down beneath the swinging pendulum.

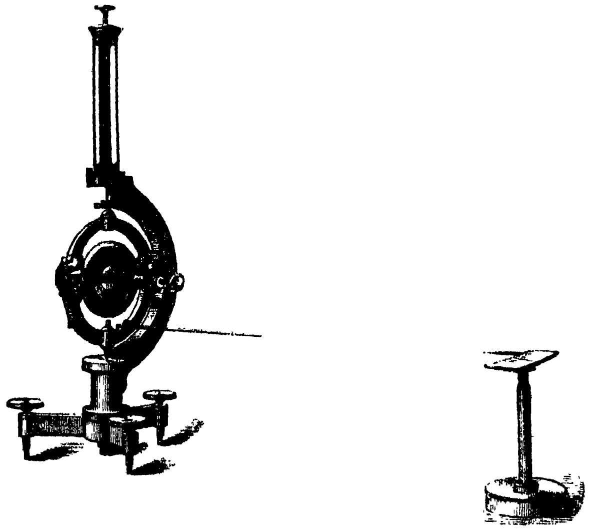

FIG. 29.—Gyroscope; general view.

From these considerations it became evident to Foucault that, if there were any possibility of demonstrating the movement of the earth by means of the pendulum, the demonstration would take this form. Provided it were possible to swing a pendulum so that it should be as free as possible from any influence due to the rotation of the earth, and take that pendulum to the north pole, it would appear to make a complete swing round the earth in exactly the same time that it really takes the earth to make a complete rotation beneath it. At the south pole exactly the same thing would happen except that the surface of the earth would appear to move in the opposite direction to what it did at the north pole. Now it will be perfectly clear that if we thus get a pendulum appearing to swing one way on account of the true motion of the earth at the north pole and in the opposite direction on account of the true motion of the earth at the south pole; at the equator, as we found in dealing with our model earth and model pendulum, it will not change the plane of swing either way, that is to say, the time taken by a pendulum to make a complete swing will be the smallest possible at the poles, whilst at the equator it will be infinite.

At all places, therefore, between either pole and the equator the period of swing will be different, and the time taken to make a complete swing will increase or decrease as the equator is approached or receded from. So much for theoretical considerations. Can they be put to the test of experiment, and an answer obtained from nature herself? The fact is that this idea of Foucault's is so beautifully simple that anybody can make the experiment providing he has the means of using a very long pendulum. This pendulum must be rigidly, but at the same time very independently, supported.

Beneath the pendulum, in contact with the earth, and therefore showing any movement of rotation which the latter may possess, is a board, on the centre of which the pendulum nearly rests. From the central point of this board lines are described showing so many degrees from the central line over which the pendulum bob swings. These preliminaries being arranged, let the pendulum be started. This is done by drawing it out of the vertical and tying it by a thread which is burnt when it is desired to start the experiment.

Then, in consequence of that quality the existence of which was revealed to us by the rotating disk and which is possessed by this vibrating pendulum, and in consequence of the precautions which have been taken to prevent its swing being interfered with by the motion of the earth or other perturbing influences, it should be found, if Foucault's assumption be correct, that the earth is moving beneath the pendulum. And if all the conditions of the experiment have been complied with it is found that the pendulum moves over the scale as the earth rotates beneath it. That then is one demonstration of the existence of the earth's rotation.

The question now arises whether there be any other method of determining the same thing. There is, but in answering the question in the affirmative it must be said that this second method is neither so simple nor so satisfactory as the first.

We owe it also to the genius of this same man, Foucault. It depends upon the same principles and is connected with the same series of facts as the other. But before proceeding to discuss this second experiment it will be well to consider these two tables, which have been taken from Galbraith and Haughton's "Astronomy," because they show not only what the swinging pendulum should do if it behaves properly, but also what the gyroscope, the instrument used in the second experiment, should do if it behaves properly.

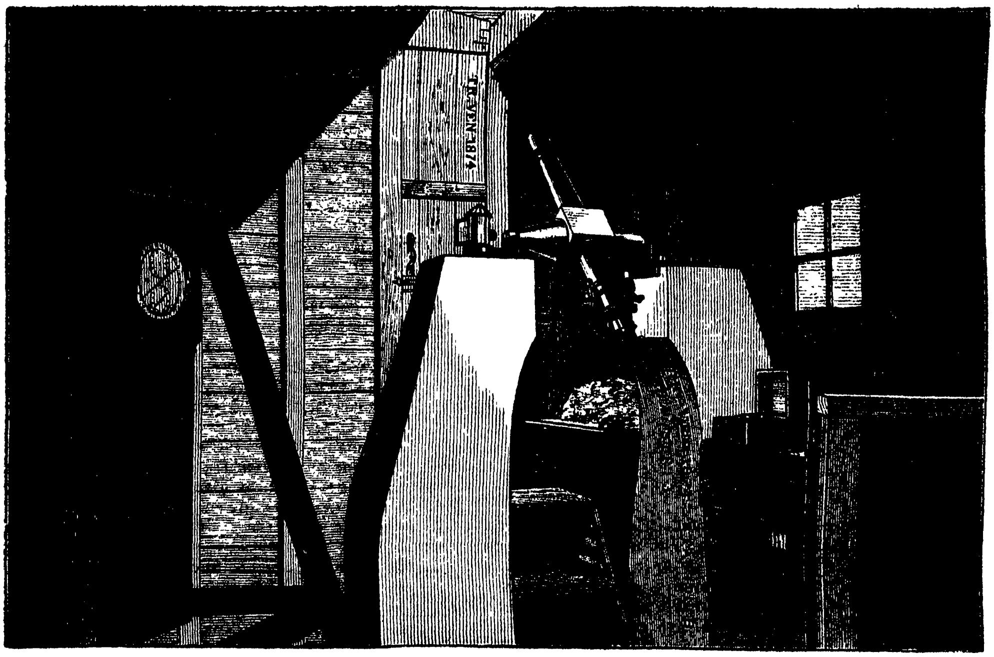

Fig. 30.—Transit instrument and clock.

The first table is called

Hourly Motion of Pendulum Plane.

Place	North Lat.	Observed motion per hour	Calculated motion per hour	Observer
Ceylon	6° 56′	1°·870	1°·815	Schaw and Lamprey.
New York	40 44	9·733	9·814	Loomis.
Providence, R.I.	40 49½	9·955	9·833	Carswell and Norton.
New Haven, Ct.	41 18½	9·970	9·929	
Geneva	46 12	10·522	10·856	Dufour and Wartman.
Paris	48 50	11·500	11·323	Foucault.
Bristol	51 27	11·788	11·763	Bunt.
Dublin	53 20	11·915	12·065	Galbraith and Houghton.
Aberdeen	57 9	12·700	12·636	Gerard.

The second is

Rotation of Earth deduced from Pendulum.

Place	Time of Rotation h.	m.	s.
Colombo, Ceylon	23	14	20
New York	24	8	9
Providence, R.I.	23	38	29
New Haven, Ct.	23	50	7
Geneva	24	41	39
Paris	23	33	57
Bristol	23	53	2
Dublin	24	14	7
Aberdeen	23	48	49
Mean value	23	53	0

The pendulum plane is of course the plane in which the pendulum swings. The first column in Table I gives the place where the pendulum was set swinging, the second the latitude, the third the observed motion per hour, and the fourth the calculated motion. The table has been so drawn up that it begins with places nearest the earth's equator and passes gradually to others further away, going from Ceylon at 6° N. lat. to New York at 40° N. lat., New Haven at 41°, and ending with Aberdeen at 57°. At the first-named place it will be seen that the pendulum swings through less than 2° per hour, whilst at Aberdeen it swings through nearly 13°, which is an approximation, at least, to the statement I have made, that, since the rotation of the pendulum plane will be most rapid at either pole, the further from the equator we swing it the greater will be the number of degrees passed over per hour.

To turn now to the gyroscope. We shall expect, if we succeed in imparting to it a rotation which is independent of and unaffected by the earth's rotation, that the angular change shown by it will be the same as that indicated by the pendulum, or, in other words, that the number of degrees passed over will be the same in both cases.

In the gyroscope, that portion which corresponds to the swinging part of the pendulum is the heavy disk seen in Fig. 28, to which a very rapid rotation can be imparted. This disk is mounted upon the horizontal circle shown in the figure, which circle in its turn is mounted in a vertical one suspended by a bundle of raw silk fibres which depend from the little screw shown at the top, by means of which the whole system can be raised, so preventing the vertical circle from resting its whole weight upon the pivot below, the use of which is not so much to support the apparatus as to guide it in its movements.

Now in order that the rotation of the disk shall be uninfluenced by the motion of the earth a great number of precautions have to be taken. The first of these is to insure that the whole of the apparatus shall be perfectly free to rotate, and that, however much the silk fibres supporting the vertical circle may be screwed up in order that it may not rest its weight upon the pivot, its motion shall not be interfered with—that there shall be no twist in the thread. This is the first precaution; and, when this has been done, a condition of things is obtained in which the apparatus is perfectly free to move round a vertical axis represented by the silk fibres prolonged. Then, having fulfilled this condition, the next matter of importance is to see that the disk is perfectly free to move on the horizontal axis. For this purpose the wheel which holds the two extremities of the axis of the rotating disk is armed with counterpoise weights (see Fig. 28), two in a horizontal plane, A A, and two in a vertical plane, of which one is seen at B.

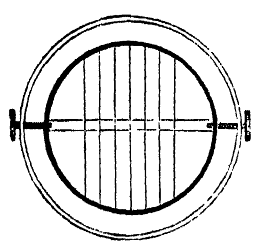

Fig. 31.—Wires in transit eyepiece.

Then the knife edges, C C, which are exactly in the plane of the centre of motion of the whole system, are made to rest on two steel plates mounted on a separate stand, in order to ascertain if the moving parts are perfectly balanced, the perfection of balance being determined by the slowness with which it oscillates up and down. But this is not all; it must not only be so adjusted by these weights, A A, that the ring shall remain horizontal, but it must be so perfectly balanced by the two weights, one of which is seen at B in Fig. 28, that if a considerable inclination be made from the horizontal it will be taken up equally on both sides. Finally, the instrument must be so adjusted that when the two delicate knife edges are placed on the two steel plates in the outer ring (see Fig. 28) the ring carrying the disk shall be perfectly free to move and have its centre of motion exactly identical with the centre of motion of the outer ring and of the disk itself. Then, when all these precautions have been taken, and the disk is set rotating with considerable velocity by means of a multiplying wheelwork train, we have, as far as the mechanics of the thing are concerned, an experiment just like the other, with this important difference, however, that, whereas the pendulum experiment always succeeds, much trouble is often experienced in experimenting with the gyroscope. But, when the multiplicity of the conditions necessary to the success of the experiment is considered, this is not surprising. If, however, all the conditions have been adhered to, the pointer with which the instrument is fitted (see Fig. 29) ought to move over the scale at exactly the same rate that the pendulum moves over the scale beneath it. But even supposing that the pointer of the gyroscope does move over the paper and in the right direction when the apparatus rotates one way, this is not enough. The demonstration of the validity of the result given by it is that an equivalent deviation is obtained when the apparatus is turned about in every possible direction. The first test of course is to rotate in the opposite way, then, if all the adjustments have been properly made, the deviation obtained will be the same in amount and direction as before, and it may be taken that the result obtained is then really due to the earth's rotation.

With this reference to the most important points connected with the gyroscope, we may bring our inquiries under this head to a close. So many men have worked with the instrument in so many lands, and under such rigid conditions, that there can be no doubt that the rotation of the earth is demonstrable by it, although certainly its verdict is not anything like so sharp, or so clear, or so easily obtained, as that given by the pendulum.

Our appeal to physics has at once put out of court the old view of the arrangement of the universe, which placed an immovable earth at its centre. How Copernicus was the first to point out that this old view was incorrect, and that it was the earth which moved, and how Galileo was persecuted because he, in times much less fortunate than our own, had the courage to say so,—these are familiar points in the history of the discovery of the earth's rotation.

Having then demonstrated the existence of this particular movement of the earth, we must now proceed to a consideration of the rate, direction, and results of the movement,—connect in fact the pendulum of Foucault with that of Huyghens, and regard the physical pendulum as giving an important use to the experiments of Galileo and of Huyghens in which they caused it to act as a controller of time.

Turn back to our two tables. They are not without interest at the present moment. In the first table, "Hourly Motion of Pendulum Plane," the observed motion of the pendulum plane per hour is connected with the latitude of the place at which it swings, varying as that varies; and therefore the observed motion in any latitude ought to give the same value for the earth's rotation, the closeness of which to the real value will at the same time be a measure of the accuracy of our pendulum observations.

Let us endeavour then to find out in what time the earth must go round in order that the pendulum plane may vary (say) $1\frac{8}{10}^{\circ}$ per hour in Ceylon, $11\frac{9}{10}^{\circ}$ in Dublin, and so forth.

Taking our clock as being divided into twelve hours, each hour into sixty minutes, and each of these again into sixty seconds, it is found (see Table 2) that the value for Ceylon is 23h. 14m. 20s., and for Dublin 24h. 14m. 7s., the mean value of the observations at the various places mentioned in the table being 23h. 53m., so that according to that table the earth rotates on its axis in a few minutes less than twenty-four hours.

Now although such an approximation to the real value may suffice for the great mass of mankind, it is not an astronomical way of dealing with the question. We have seen the circumference of a circle divided first into degrees, then into $\frac{1}{8}$ degrees, next into seconds, and finally into tenths of seconds; by the application of electrical principles, time has been even more finely divided, and the question naturally arises, Are there any means of determining the exact period of the earth's rotation?

There are means of doing this. In the last lecture occasion was taken to point out that the stars are infinitely removed from the earth; the stars being so infinitely distant, a slight change in their position will not be perceptible to an observer on the earth, and the place of a star to-day and its place to-morrow are the same so far as relates to any parallactic change of position.

This being premised, it will be clear that, in order to get out the exact period of the earth's rotation, one only has to make an observation of any star on one particular day (such observation being of course made with a clock), and repeat the observation when the star is in the same position on the succeeding day. The time which elapses between the observations must be the time taken by the earth to make a complete rotation. But it will be asked, How are these observations made, and how is it known when the star *is* in the same position when the second observation is made?

For this purpose a transit instrument is used (see Fig. 30). This differs from an ordinary telescope, being so mounted as to move only up and down, and is armed not with simple cross wires, but with an odd number of parallel and equidistant vertical wires crossed by a single horizontal wire. It is also usually provided with a circle to give declination. If from any part of the earth an observation be made on any particular star on one day, and then another observation made on the same star when it is in the same position the next day, as has been said, the interval between the two observations must be the time taken by the earth to move round once.

By having such an arrangement as exists in the transit instrument, by which it can swing in the plane which coincides with the axis on which the earth turns, any star may be chosen for the observation. Suppose, for instance, the instrument be pointed to the north pole star, then, in consequence of the tremendous distance of the stars, the axis of the telescope is practically coincident with the axis of the earth. But suppose another star to be observed, it will be quite clear that we may make the observation on it, or any other star we choose. When the instrument is upright it points to the zenith. A star in the zenith may therefore be selected for the observation.

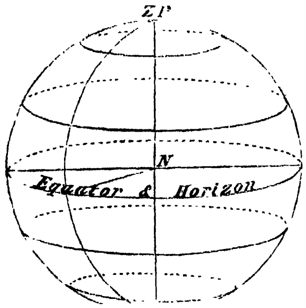

FIG. 32.—Showing that the true horizon of a pole is the equator.

It is observed when crossing the central wire of the instrument one day, and noted again when it crosses that wire on the succeeding day. But the observer does not limit his observation to the one central wire, in order to ascertain when the star is in the centre of the field. If he did so, he might miss his observation. That is why the simple cross wires have been replaced by a system of wires (see Fig. 31). As the star crosses the field of view, the observer, listening to the beats of the clock alongside, notes the time when it crosses each of the wires, and takes the mean of these observations, thus attaining to a much greater accuracy than if he had merely observed the transit over the central wire. With an ordinary clock it is found that a period, less by a few moments than twenty-four hours, elapses between two successive transits.

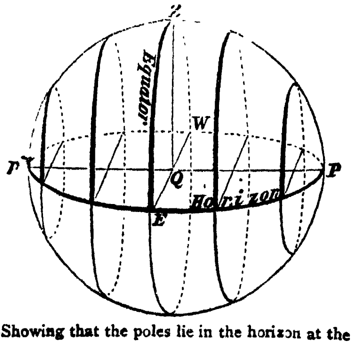

FIG. 33.—Showing that the poles lie in the horizon at the equator.

In order to get an absolutely perfect measure of time, the clock may be so rated that it should not be any indeterminate number of hours, minutes, and seconds, but twenty-four hours exactly between the two transits of that star. With a clock thus arranged, the time at which a star crossed the central wire of the transit instrument would really give a most perfect method of determining that star's place in the heavens, because, if the earth's rotation is an equable one and takes place in a period which we choose to call twenty-four hours, then two stars 180° apart will be observed twelve hours after one another, four stars 90° apart will be observed six hours apart, and so on; and clocks like this, regulated to this star time, exist in our observatories, being called sidereal clocks, because the time they give, which is not quite familiar to everybody, is called sidereal time.

Now let us consider our position on the earth with regard to the stars. This is a very interesting part of our subject, not only in its scientific aspect, but from the point of view of its usefulness, whether we wish to study the stars or define places on the earth's surface, the latter matter, however, being so intimately connected with astronomy proper that it is impossible to talk about the one without talking about the other.

Since we divide all circles into 360°, the circumference of the earth may be so divided, and the method in use of defining positions on the earth is to say of a place that its latitude is so much and its longitude is so much. Latitude begins at the equator with 0°, and terminates at the poles with 90°, being north latitude in the one case, and south latitude in the other. In the case of longitude, there is no such simple starting point, for whilst latitude is counted from the equator by everybody all over the world, longitude may commence at any point. In England we count longitude from the meridian of Greenwich. When the transit instrument at Greenwich is swept from the north point through the zenith to the south point it describes a half circle, which is called the meridian of Greenwich.

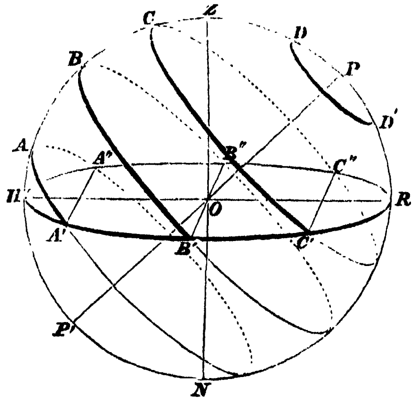

FIG. 34.—Horizon of a place in mid-latitude.

That is one point. Another point is this. Suppose the instrument to be set up not at Greenwich but at the north pole. Then the true horizon of the observer will be along the equator. Remove the instrument to the equator, and the true horizon will cut the poles. At a place in mid-latitude the true horizon would cut neither the pole nor the equator, but would be inclined to both (see Figs. 32, 33, and 34).

Then comes the important relationship between the latitude of the place and the altitude of the pole star above its horizon; that the number of degrees this star—be it north or south—is above the horizon of the observer will be the number of degrees of north or south latitude of the place where the observation is made. A place therefore in 10° N. lat. will (roughly) have the north pole star at a height of 10° above its horizon.

So much for this part of our subject. Let us now leave it, because, interesting as it is, it refers to a branch of astronomy with which at present we have less to do than with the more physical one; but it was well that we should pause for a few moments to note the tremendous importance to mankind of that particular movement of the earth which we have been considering.

J. NORMAN LOCKYER

(*To be continued.*)

PROBABLE NATURE OF THE INTERNAL SYMMETRY OF CRYSTALS[1]

THE theory of the modification of crystal angles, just offered in dealing with quartz, is manifestly applicable to all crystals not of the cubic system, and it is submitted that for every such crystal there is an *ideal* or *root form* proper to one or other of the five kinds of internal symmetry which have been presented, from which root form the actual form can be derived by a proper proportionate increase of dimension in one or more directions.

---

[1] Continued from p. 188.

It is evident that, while our path must become more and more intricate as we endeavour to establish in the cases of more complex compounds relations similar to those above traced, the reference of whole classes of analogous forms, differing only in their angles, to one root form, removes a very important difficulty, and the wide applicability which it confers on the five kinds of internal symmetry with which we started appears in the fact that there is no crystal form which cannot be thus referred to an appropriate root form in harmony with one or other of these five kinds of internal symmetry.[1]

One more case may be mentioned in which a probable internal symmetry can be assigned to a compound in harmony with its actual crystal form; it is a more difficult one.

The molecule of *Iceland* or *calc-spar* is usually believed to consist of one atom of calcium, one atom of carbon, and three of oxygen. We shall, however, take a liberty, and suppose that the atoms of calcium or the atoms of carbon have but half the mass attributed to them; that in the formula of this compound we should write either two atoms of calcium or two atoms of carbon in place of one.[2]

Making this supposition, we observe that if the calcium and carbon atoms were alike we should have six atoms, three of one kind, three of another; in other words, we should have equal proportions of two kinds of atoms, from which, since the form of Iceland spar is but little removed from a cube, we naturally argue that just before crystallisation its atoms were arranged according to the first or second kind of internal symmetry; these two kinds being, it will be remembered, those in harmony with the cubic form which admit of very symmetrical arrangement of particles of two kinds present in equal numbers.

Since Iceland spar is a uniaxal crystal, the arrangement of the three kinds of atoms, whatever it is, must be symmetrical about one axis only; and we shall now endeavour to show that the atoms can be thus arranged in either the first or second kind of symmetry.

We will show first that they can be thus arranged in the second kind.

Where there are but two kinds of particles present in equal numbers, symmetry requires that the alternate layers of this kind of symmetry (see Fig. 3) shall consist entirely of similar kinds, and therefore in the case before us, one set of alternate layers will represent oxygen atoms; the other, atoms of calcium and carbon. Now particles present, as we suppose the calcium and carbon atoms to be, in the proportion 1 : 2 can be quite symmetrically arranged in these layers (plan *f*), as the sphere centres were in the layers depicting the fourth kind of symmetry (plan *e*), and therefore the only question remaining is the relative disposition of the layers of calcium and carbon atoms with respect to one another.

Now the spheres in alternate layers of the second kind of symmetry considered alone have the relative arrangement of the third kind of symmetry (Fig. 4), and in determining the relative disposition of the calcium and carbon atoms, we may therefore neglect the oxygen atoms, and treat the case as belonging to the third kind of symmetry. The two spiral arrangements in this kind of symmetry, in which the less numerous spheres in the fourth layer are vertically over those in the first (see *ante*), have the necessary symmetry about a single axis, and if the calcium and carbon atoms have one of these arrangements, the requirements of the case are entirely met.

We will now show that the three kinds of atoms can also be arranged symmetrically about a single axis in the first kind of symmetry.

One half the spheres depicting this kind of symmetry will in this case represent the oxygen atoms, and the remaining half the atoms of calcium and carbon (see Fig. 2), and, as previously noticed, the arrangement of either half will be that of the second kind of symmetry. It follows that the question of the relative disposition of the atoms of calcium and carbon is simply the question of the symmetrical arrangement about a single axis of atoms of two kinds present in the proportion 2 : 1 in the second kind of symmetry (Fig. 3). And since the layers of spheres depicting this kind of symmetry have a triangular arrangement (plan *b*), it is evident that this can be accomplished here just as in the former case.

In either of the two arrangements just described we have only to suppose that when the symmetrically placed atoms change volume at the time of crystallisation the dimensions transversely to the axis of symmetry are increased relatively to those in the direction of this axis, and we have an obtuse rhombohedron where formerly we had a cube. And the significant fact that the angle of a rhombohedron of calc-spar diminishes when the crystal is heated supports this theory of its production. Perhaps the arrangement of the atoms according to the first kind of internal symmetry is the more probable of the two, as this would give the cleavage directions coincident with the directions of layers of similar atoms (oxygen).

An important fact supporting our conclusions is that certain definite relations as to their proportions which are found subsisting between the allied forms taken by crystals of the same substance are found inherent in one or other of the five kinds of internal symmetry.

Thus it is well known that if a particular substance is found crystallised in hexagonal pyramids of various kinds—that is, whose sides have various different degrees of inclination to the base—the number of kinds is strictly limited, and they are strictly related to each other. If x be the side of the hexagonal base of the pyramid and y the height for the same substance, while x remains constant, y has not more than fourteen different values, seven related thus: c, $\frac{3}{4}c$, $\frac{1}{2}c$, $\frac{1}{4}c$, $\frac{1}{8}c$, $\frac{1}{12}c$, $\frac{1}{16}c$; and the other seven similarly related thus: d, $\frac{3}{4}d$, $\frac{1}{2}d$, $\frac{1}{4}d$, $\frac{1}{8}d$, $\frac{1}{12}d$, $\frac{1}{16}d$; and c bearing to d the ratio $2 : \sqrt{3}$.

Now, if we turn to the fourth kind of internal symmetry (Fig. 5) to ascertain the possible varieties of inclination of the sides of hexagonal pyramids which can be depicted, we find that the greatest possible height to which we can build a hexagonal pyramid of equal spheres is exactly double the height of a tetrahedron with the same side as the hexagonal base of the pyramid. Thus, if twenty-five spheres form each side of the hexagonal base, giving twenty-four equal distances between the sphere centres in any one side, we find that the highest possible pyramid has forty-nine layers of spheres giving forty-eight equal spaces between consecutive layers.

If we call this height c, it is evident that pyramids corresponding with the first of the above series of actually observed forms will have respectively—

49	layers of balls, giving	48	spaces between consecutive layers.
37	,, ,,	36	,, ,,
25	,, ,,	24	,, ,,
13	,, ,,	12	,, ,,
7	,, ,,	6	,, ,,
5	,, ,,	4	,, ,,
4	,, ,,	3	,, ,,

We find, moreover, that such a series can be readily depicted, and that, upon examination, no additional terms appear admissible.

Again, a further inspection of the stack of spheres shows us that with the same heights—that is, with the respective numbers of layers just enumerated—we may, in place of the base layer which forms a hexagon whose sides have twenty-five spheres each, have a base derived from this in which each of the six spheres at the angles becomes the centre of a side, the outline of the base layer being now a larger hexagon described about the hexagon which bounded the former base layer. The sides of this new base thus bear to the sides of the old the ratio subsisting between the side and the perpendicular of an equilateral triangle, *i.e.* the ratio $2 : \sqrt{3}$. And finally, since the distance between the planes containing the centres in successive layers bears to the distance between centres in the same layer the same ratio which the perpendicular from the angle of a tetrahedron upon its opposite face bears to its edge, that is the ratio $\sqrt{2} : \sqrt{3}$, it follows—

That the two allied series of possible altitudes of hexagonal pyramids thus formed, if we take *the same length of side a* for both, will be—

First Series

$$\frac{2\sqrt{2}}{\sqrt{3}}a;\ \frac{3\sqrt{2}}{2\sqrt{3}}a;\ \frac{\sqrt{2}}{\sqrt{3}}a;\ \frac{\sqrt{2}}{2\sqrt{3}}a;\ \frac{\sqrt{2}}{4\sqrt{3}}a;\ \frac{2\sqrt{}}{6\sqrt{3}}a;\ \frac{\sqrt{2}}{8\sqrt{3}}a.$$

Second Series

$$\sqrt{2}.a;\ \tfrac{3}{4}\sqrt{2}\,a;\ \tfrac{1}{2}\sqrt{2}.a;\ \tfrac{1}{4}\sqrt{2}\,a;\ \tfrac{1}{8}\sqrt{2}\,a;\ \tfrac{1}{12}\sqrt{2}\,a;\ \tfrac{1}{16}\sqrt{2}.a.$$

---

[1] The very symmetrical form the pentagonal dodecahedron is not in harmony with either of the five kinds of symmetry, nor is it found in crystals.

[2] It has already been remarked that the crystal form of fluor-spar favours the supposition that calcium has half the atomic weight usually attributed to it.

Surely the fact thus established, that each term of a series of relative altitudes of the hexagonal pyramids in which a particular substance crystallises always has to some term of the series thus theoretically derived a particular ratio peculiar to the substance, constrains us to conclude that the above fourteen "root" forms are those to which all crystal forms involving regular six-sided pyramids are referable, and that the actual forms are produced from the "root" forms by difference in the degree of expansion in the direction of the axis of the crystal as compared with other directions at the time of crystallisation.

Other allied forms, as allied octahedra or rhombohedra, can be in the same way connected with some one of the five kinds of internal symmetry.

The peculiarities of *crystal-grouping* displayed in twin crystals can be shown to favour the supposition that we have in crystals symmetrical arrangement rather than symmetrical shape of atoms or small particles. Thus if an octahedron be cut in half by a plane parallel to two opposite faces, and the hexagonal faces of separation, while kept in contact and their centres coincident, are turned one upon the other through 60°, we know that we get a familiar example of a form found in some twin crystals. And a stack can be made of layers of spheres placed triangularly in contact to depict this form as readily as to depict a regular octahedron, the only modification necessary being for the layers above the centre layer to be placed as though turned bodily through 60° from the position necessary to depict an octahedron (compare Figs. 7 and 8). The modification, as we see, involves *no departure from the condition that each particle is equidistant from the twelve nearest particles.*

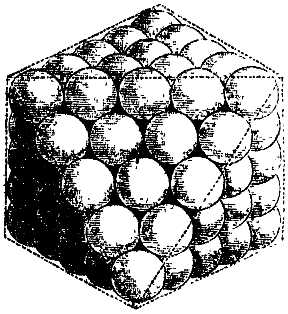

FIG. 7.

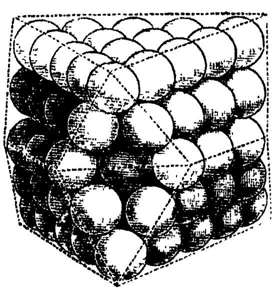

FIG. 8.

Before closing, a few words may be said on the bearing of the conclusions of this paper on *isomorphism* and *dimorphism*.

First, as to isomorphism.

The conclusion that there are but five kinds of internal symmetry possible, three of which indicate a cubic form, evidently accords with the fact that not only the simplest combinations—those in which two kinds of atoms are present in equal proportions—but also many very complicated compounds crystallise in cubes.

Out of the regular system we generally find that for the angles of crystals of different compounds to be the same there must be some resemblance in their atom-composition, and the explanation suggested is that the atoms which are common to two isomorphous compounds, *e.g.* the carbon and oxygen atoms in calc-spar and spathic iron ore, have similar situations in the two different crystals, and that the change of bulk which occurs when crystallisation takes place is due to a change in *these atoms only*, the atoms not found in both remaining *passive*.

There are, however, some cases which do not at first seem to be met by this view—cases in which the atom composition of isomorphous compounds has only a very partial similarity. Ammonia compounds may be specially mentioned. Thus, ammonic sulphate, $(NH_3)_2H_2SO_4$, is isomorphous with potassic sulphate K_2SO_4.

The following suggestion would seem to enable us to suppose that in this, as in other cases of isomorphism, the phenomenon is referable to the passivity of some of the atoms in the change of bulk which accompanies crystallisation. Let us write ammonic sulphate thus $(NH_3)_2H_2SO_4$, and let us suppose that the symmetrical arrangement is such that the groups, $(NH_3)_2$ just occupy places which might, without altering the symmetry, be filled by additional groups H_2SO_4; that, in other words, the relative position of the groups H_2SO_4 which are present in the symmetrical arrangement is precisely the same as it would be if the entire mass consisted of these groups instead of consisting partly of NH_3 groups. If now, in addition to supposing that in both compounds the active atoms in the process of crystallisation are the sulphur and oxygen atoms, and these only, we suppose that the expansion of some of the atoms of the active kind checks the expansion of others; that only a certain proportion of these atoms expands, we perceive that we may have both the same amount and kind of atom expansion in the two cases, and, as the natural result, isomorphism.

Next, as to dimorphism.

It is evident that a very small change is requisite to convert one kind of internal symmetry into another. Thus we have already had occasion to notice that the only difference in depicting the third and fourth kinds of symmetry is that for the former the centres of the spheres in the first and fourth layers, those in the second and fifth, and so on, range vertically, while for the latter the centres in the first and third, in the second and fourth, and so on, range in this way.

In the case of a dimorphic compound consisting of two kinds of atoms in the proportion of 2 : 1, *e.g.* water, H_2O, we have only to suppose therefore that the same layers of atoms which under one set of conditions produce hexagonal prisms, are by some alteration in conditions arranged in the slightly different way necessary to produce rhombohedral forms. Other cases of dimorphism are probably to be accounted for much in the same way.

Thus the following interpretation of the fact that calcic carbonate, which we have seen crystallises in obtuse rhombohedra as calc-spar, sometimes crystallises in six-sided trimetric prisms as aragonite may be offered.

We have already endeavoured to show that the first or second kind of internal symmetry is that proper to calc-spar. We will now endeavour to show that the fifth kind of internal symmetry (Fig. 6) is proper to aragonite.

Alternate layers of spheres (plan *b*) will represent the oxygen atoms, and the other alternate layers the calcium and carbon atoms; the central layers of the triplets above alluded to, viz. the second, the fourth, the sixth, &c., being the oxygen layers; the calcium and carbon atoms in the remaining layers will be symmetrically arranged (plan *f*). From the fact of the crystals being trimetric, the layers containing the last-named atoms, which, considered apart from the oxygen layers, are in the fourth kind of symmetry, probably have the arrangement above described, in which the less numerous spheres form zigzags, the stack in this case having a different symmetry about three axes at right angles to each other (Fig. 6).

The fact that the dimorphic varieties of the same substance have different densities is in harmony with the supposition that different sets of the atoms are concerned in the different cases; that the active atoms which produce one form are not those, or those only, which produce the other.

It is not always necessary to refer two incompatible crystal forms of the same substance to two different kinds of internal symmetry: for example, from the third kind of internal symmetry we can produce square-based octahedra, and we can also produce right-rhombic prisms, and in accord with this we have the well-known fact that right-rhombic prisms of sulphate of nickel, $N_2SO_47H_2O$, when exposed to sunlight are molecularly transformed, and, though they neither liquefy nor lose their form, when they are broken are found to be made up of square-based octahedra several lines in length. WILLIAM BARLOW

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following awards (among others) have been made at St. John's College on the results of the examination for candidates who have not yet commenced residence:—

For Mathematics: H. F. Baker (Perse Grammar School, Cambridge), Foundation Scholarship, raised for two years to 75*l.* a year; A. W. Flux (Portsmouth Grammar School), Minor Scholarship of 75*l.* a year; P. T. Fagan (Highwood School, Weston), Exhibition of 50*l.* a year; H. R. Norris (University College School), Exhibition of 30*l.* a year.

For Natural Science: G. S. Turpin (Nottingham High School and Owens College, Manchester), Foundation Scholarship raised for two years to 75*l.* a year; P. Lake (Newcastle College of Science), Minor Scholarship of 75*l.* a year; W. Harris (Bradford Grammar School), Exhibition of 50*l.* a year; W. M. Mee

(Trinity College, Dublin), Exhibition of 32*l.* a year [Mathematics and Physics].

For Hebrew: G. C. Ewing (Merchant Taylors' School, London), Exhibition of 33*l.* 6*s.* 8*d.* a year.

SOCIETIES AND ACADEMIES

LONDON

Royal Meteorological Society, December 19.—Mr. J. K. Laughton, M.A., F.R.A.S., president, in the chair.—The following were elected Fellows:—R. Bentley, W. Bonallo, Miss E. Brooke, Rev. A. Conder, T. H. Cowl, J. A. W. Oliver, C. M. Powell, W. B. Tripp, and Fung Yee. The papers read were:—On the explanation of certain weather prognostics, by the Hon. Ralph Abercromby. The author explains about forty-four well-known prognostics belonging to the following groups—(1) diurnal; (2) sun, moon, and stars; (3) sky; (4) rain, snow, and hail; and (5) wells, springs, and coal-mines—by referring them to the isobaric conditions in which they are observed. By this means he is able to indicate the circumstances under which any prognostic fails, as well as those under which it succeeds.—Preliminary inquiry into the causes of the variations in the reading of black-bulb thermometers *in vacuo*, by G. M. Whipple, B.Sc. It has long been known that there is a want of accordance between the different instruments used for measuring the intensity of radiation, and with a view of ascertaining the cause of the variations in the readings of the black-bulb thermometers *in vacuo*, the author has made a comparison with a number of these thermometers, the results of which are given in the paper. It is shown distinctly that the effect of an increased coating of lamp-black on the bulb is to raise the temperature, and also that the size of the thermometer-bulb is a most important factor in the case of this instrument.—Report on the phenological observations for 1883, by the Rev. T. A. Preston, M.A.—Mr. J. S. Dyason exhibited a series of coloured sketches illustrating the recent atmospheric phenomena during November and December.

Geological Society, December 5.—J. W. Hulke, F.R.S., president, in the chair.—George Jonathan Binns, Horace T. Brown, James Dairon, Rodolph De Salis, Hugh Exton, John Forrest, Prof. Bernard J. Harrington, James Patrick Howley, John Sylvester Hughes, Prof. George T. Kennedy, Rev. Arthur Noel Malan, Robert Sydney Milles, Edwin Radford, Edward Pierson Ramsay, William Henry Rands, Thomas Roberts, Joseph Ridgway, and Harry Page Woodward were elected Fellows of the Society.—On the Cambrian conglomerates resting upon and in the vicinity of some pre-Cambrian Rocks (the so-called intrusive masses) in Anglesey and Carnarvonshire, by Henry Hicks, M.D., F.G.S. In a former paper the author had maintained that there was no evidence to show that the so-called intrusive granite in Anglesey had altered the Cambrian and Silurian rocks in its immediate vicinity, or that they had been entangled in it as described, but that it seemed to be a rock of metamorphic origin, varying much in its general appearance at different points. He contended that, instead of being an intrusive granite, as supposed by the officers of the Survey, it was in all probability the oldest rock in Anglesey. The basal Cambrian conglomerate in contact with it is in an unaltered condition, and at Llanfaelog contains an extraordinary proportion of well-rolled pebbles, identical in mineral composition with the so-called granite immediately below. Fragments of all the varieties of rock found in the granitoid axis are recognisable in the conglomerate, and in precisely the same condition as in the parent rock. Fragments of the various schists of the area were also present; so that he thought there cannot be the shadow of a doubt that the so-called granite and the metamorphic schists are older than the conglomerate, and therefore pre-Cambrian. The view maintained by the Survey that the schists are altered Cambrian and Silurian strata, and the granitoid rock an intrusive granite of Lower Silurian age, is consequently quite untenable. In Carnarvonshire equally conclusive evidence was obtained from many areas. Fragments of the Dimetian (Twt Hill type) occurred abundantly in the basal Cambrian conglomerates at Dinas Dinorwig, Pont Rothel, Moel Tryfane, and Glyn Llifon. Quartz-felsite pebbles in every respect identical with the varieties found in the so-called intrusive ridges between Bangor and Carnarvon, and to the north and south of Llyn Padarn, were found on the shores of the Menai Straits, in the railway-cutting at Bangor, at Llandeiniolen, Dinas Dinorwig, Llyn Padarn, and elsewhere. This evidence, supplementary to that previously furnished by Prof. Hughes, Prof. Bonney, and the author is conclusive as to these areas, since the basal Cambrian conglomerates, which are in contact with these supposed intrusive masses, are composed almost entirely of rocks identical with the latter; and this could not possibly be the case if the granitoid masses had been intruded among the conglomerates after their deposition.—On some rock-specimens collected by Dr. Hicks in Anglesey and North-West Carnarvonshire, by Prof. T. G. Bonney, F.R.S., Sec.G.S. The author stated that pebbles in the blocks of conglomerate collected by Dr. Hicks to the north of Llanfaelog were practically undistinguishable macroscopically and microscopically from the granitoid and gneissic rocks which occur *in situ* between that place and Ty Croes, and that the matrix contained smaller fragments, probably from the same rock, with schist bearing a general resemblance to members of the group of schists so largely developed in Anglesey, and with grits, argillites, &c. Pebbles of granitoid aspect in the Cambrian conglomerate near Dinas Dinorwig, &c., bear a very close resemblance to the Twt Hill rock, and are associated with abundant rolled fragments of rhyolite resembling those already described from the Cambrian conglomerate and the underlying conglomeratic beds and rhyolites. Two pebbles of rather granitoid aspect in the Cambrian conglomerate by the shore of the Menai Straits, near Garth, prove to be spherulitic felsite, somewhat resembling that already described by the author from Tan-y-maes. He pointed out that the evidence of these specimens collected by Dr. Hicks, added to that already obtained, led irresistibly to one of two conclusions—either that, when the Cambrian was formed, an area of very ancient metamorphic rock was exposed near Ty Croes and in the Carnarvonshire district, or that the rhyolitic volcanoes were so much older than the Cambrian time that their granitic cores were already laid bare by denudation. Hence, in either case, the existence of Archæan rock in North Wales was proved. To one or other of these conclusions he could see no possible alternative, and he considered the former to be (even if some of the granitoid rock were granite) far the most probable.—On some post-Glacial ravines in the Chalk Wolds of Lincolnshire, by A. J. Jukes-Browne, F.G.S.

EDINBURGH

Mathematical Society, December 14.—Mr. Thomas Muir, president, in the chair.—Mr. J. S. Mackay read a paper on the medioscribed circle of a triangle with its analogous and associated circles viewed from their centres of similitude.—Prof. Chrystal stated some propositions in geometry for which he wished proofs.—Mr. Muir made a communication on determinants with *p*-termed elements.—The Secretary gave a new construction by the Rev. G. McArthur for Euclid ii. 9, 10; and Mr. James Taylor Dollar proposed for solution a theorem in elementary geometry.

THERMAL CHEMISTRY

Thermochemische Untersuchungen. Von Julius Thomsen, Dr. Phil. et Med., &c. Volumes I., II., and III. (Leipzig: Johann Ambrosius Barth, 1882-83.)

A PAPER was published in this journal a short time ago calling attention to "The Backward State of Chemistry in England" (vol. xxviii. p. 613); the writer regrets that so little attention is paid to the chemistry of the carbon compounds, and that so much time is spent in our chemical schools in elementary and routine instruction. In the second of these regrets I can thoroughly sympathise; our so-called students of chemistry are becoming mere machines which perform, and generally perform badly, mechanical processes known as qualitative and quantitative analyses. We hear complaints from physical laboratories that practical physics is taught in an unsystematic manner; we sometimes have comparisons drawn between the desultory methods of teaching pursued in these laboratories and the orderly and systematic courses of practical chemistry conducted in the workrooms of the sister science. But I am afraid it is rather the chemist who is to be pitied: his method is too methodical; it seems to succeed because it neglects the really scientific aspects of chemistry. Chemistry is a great branch of science; but what is the so-called practical chemistry of the schools or the examination? It is but a weary round of dull repetition; it consists of obtaining black precipitates, and yellow precipitates, and colourless precipitates, precipitates which are soluble and those which are insoluble; it occupies itself with filtering and washing, and drying, and burning, and weighing; it has little or no connection with the problems which belong to the science of chemistry. But when the author of the article to which reference has been made attributes the backward state of chemistry in England to the comparatively small amount of attention which is given to organic chemistry, I find myself unable to agree with him. I think we are apt to be dazzled by such things as the synthesis of indigo, or the artificial manufacture of alizarin: we forget to inquire whether the study of organic chemistry has in recent years added any great general principle to chemical science. The conception of the valency of elementary atoms is certainly an outcome of the study of the carbon compounds, or rather of the application of the atomic theory to this study; but have we not of late made too much of this conception? has it not rather stopped than aided inquiry? is it not time we had given up our "bonds," our "units of affinity," which are chiefly remarkable as being changeable almost at pleasure? Organic chemistry, as pursued in the German laboratories, it seems to me, has almost if not quite entered on the same path as that which has led qualitative and quantitative analysis to so sad a fall: it is in danger of ceasing to be a branch of science and of becoming an art of manufacture. Any student who goes through the course of preparation of organic compounds, systematised so well in the laboratories of the German universities and elsewhere, is ready to manufacture new compounds by the score; the difficulty consists in not making such compounds. There are whispers abroad that he who is not in the trade is regarded by the German professors as "no chemist."

I think the evil lies deeper: we are so anxious to act that we have no time to think. The chemist may gain a kind of reputation by making new compounds; the process requires no thought, no scientific training, no originality. It has also something to be said in its favour. Nature is so vast that we can scarcely hope to gain any accurate knowledge save by attacking the problems in detail. In chemistry, as in other branches of science, we must be content to gain "a series of small victories" over nature. But in fighting nature in detail we are apt to lose sight of general principles by the help of which alone can empiricism become science. I think that in chemistry, and more especially perhaps in organic chemistry, we are specialising too much: we are trying to solve large and complex problems by a series of small attacks all delivered from the same point. What then is the remedy? I would answer: Vary the points of attack; remember that the victory is to be gained only by boldness, and that it is emphatically worth gaining. Do not let chemistry remain the battlefield of the Philistines, but enliven it with the true spirit of science, with that spirit which will not believe that the universe is a "rubbish-heap of confused particulars," but will rather regard it as a vast organism in which while "everything is distinct yet [is] nothing defined into absolute independent singleness."

That the points from which the problems of chemistry may be attacked are many is witnessed by the book before us. Why is there no handbook of thermal chemistry in English? Will not some one at least translate Naumann's "Handbuch"? M. Thomsen has for years been known as one of the two great workers in the field of thermal chemistry; his contributions to this branch of science have been numerous and important; we cannot be too thankful that he has gathered these contributions together, and arranged and digested them in this series of volumes, which must remain as the groundwork of the science. Three volumes have appeared, and a fourth (to treat of organic compounds) is promised. Let me try to give some account of one or two points in Thomsen's work.

The notation of thermal chemistry is simple: Let r = the thermal value (stated in gram-units) of a chemical change; if the change consist in the formation of a definite quantity of a compound $X_a\,Y_b\,Z_c$—made up of *a* parts of X, *b* parts of Y, and *c* parts of Z—then

$$r = [X^a, Y^b, Z^c] + ;$$ [1]

if the same compound is produced in presence of a large quantity of water, then

$$r = [X^a, Y^b, Z^c, Aq] + ;$$

if the same substance already formed is dissolved in an unlimited quantity of water, then

$$r = [X^a\,Y^b\,Z^c, Aq] + .$$

The general expressions for the production and decomposition of a compound $X_a\,Y_b$ are

$$(1)\ X_a + Y_b = X_a\,Y_b + (X^a, Y^b);$$

and

$$(2)\ X_a\,Y_b = X_a + Y_b - (X^a, Y^b).$$

---

[1] Thomsen always writes the indices above the elementary symbols when these symbols occur in thermal equations

If the compounds X Y and Z V react to produce X Z and Y V then

$$r = [X, Z] + [Y, V] - [X, Y] - [Z, V].$$

These equations illustrate the methods by which the thermal value of a chemical change can be indirectly calculated. The total loss of energy by a chemical system in passing from a definite initial to a definite final state is independent of the intermediate states; assuming, as we may do for most purposes, that the total loss of energy is measured by the quantity of heat evolved, it follows that the total thermal change accompanying a chemical change depends only on the initial and final states of the system. Hence, if we have series of reactions beginning with the same materials in the same condition, and ending with the same products in the same condition, and if all the thermal changes in one series may be measured, and all except one in the other series may be measured, it follows that we can calculate the thermal value of the unknown member of the second series of changes. Thus, it is required to determine the thermal value of the synthesis of 46 grams of formic acid (CH_2O_2). Twelve grams of carbon, 2 of hydrogen, and 48 of oxygen combine to produce 44 grams of carbon dioxide and 18 grams of water: but the same quantities of the same materials might theoretically be combined to produce 46 grams of formic acid, and then from this, 44 grams of carbon dioxide + 18 grams of water would be produced. The following are the thermal values of the various parts of these two series of changes:—

$$[C, O^2] = 96{,}960 \text{ gram-units} + ;\ [H^2, O] = 68{,}360 + ;$$
$$[CH^2O^2, O] = 65{,}900 + ;$$

but

$$[C, O^2] + [H^2, O] = [C, H^2, O^2] + [CH^2O^2, O] = 165{,}320 +$$
$$\therefore [C, H^2, O^2] = [C, O^2] + [H^2, O] - [CH^2O^2, O] = 99{,}420 +.$$

Such calculations sometimes become very complex; corrections must frequently be introduced for quantities of heat evolved or absorbed during purely physical changes which form integral parts of the cycle of chemical change under investigation.

The thermal study and comparison of classes of chemical changes leads to the conclusion that a chemical change which is accompanied by considerable loss of energy to the changing system will generally occur, unless prevented by the action of forces external to the system. This generalisation, vague though it be, helps to explain many classes of chemical reactions, *e.g.* the action of concentrated and dilute solutions of hydriodic acid on sulphur, and on many hydroxyl-containing carbon compounds; and the action of sulphuretted hydrogen in precipitating certain metallic sulphides in the presence of acid, and others only form alkaline liquids.

Thomsen has devoted much time and care to the thermal investigation of the mutual actions of acids and bases: the greater part of his first volume is devoted to this inquiry. The "heat of neutralisation of an acid by a base" is defined as the number of gram-units of heat evolved on mixing equivalent quantities in grams of the acid and base in dilute aqueous solution, the products of the action being also soluble in water. Thomsen employs a solution of 2 NaOH (grams) in about 200 H_2O (grams) as the standard base: he measures the thermal values of the following reactions:—

[2NaOH Aq, 2HX Aq] in the case of a monobasic acid.
[2NaOH Aq, H_2X Aq] „ „ dibasic „
[2NaOH Aq, $\frac{2}{3}H_3X$ Aq] „ „ tribasic „
[2NaOH Aq, $\frac{1}{2}H_4X$ Aq] „ „ tetrabasic „

The commoner acids may be broadly divided into four groups, according to the values of the "heats of neutralisation." This value is for Group I. about 20,000 gram-units; II., about 25,000; III., about 27,000; and IV., about 30,000 gram-units. The study of heats of neutralisation has led Thomsen to the conception of the *avidity* of an acid, *i.e.* the striving of one acid to displace another from its combination with a base. Thus, when equivalent quantities of NaOH, HNO_3, and H_2SO_4 are mixed in dilute aqueous solutions, two-thirds of the NaOH combines with the HNO_3, and one third with the H_2SO_4; the *avidity* of HNO_3 for NaOH is said to be twice as great as that of H_2SO_4 for the same base. HNO_3 in aqueous solution is therefore a *stronger acid* than H_2SO_4.

Measurements of the heats of neutralisation of monobasic, dibasic, *n*-basic acids has led Thomsen to classify some of these acids in ways different from those generally adopted in the text-books. His results as regards dibasic and tribasic acids may be thus summarised:—

Dibasic Acids

Group I. Typical formula RH_2 *e.g.* $SiF_6 . H_2$
„ II. „ „ $R(OH)_2$ *e.g.* $SO_2(OH)_2$
„ III. „ „ $R(OH)H$. *e.g.* $SO_2(OH)H$.

Tribasic Acids

Group II. Typical formula $R(OH_3)_3$. *e.g.* $C_4H_5O_4(OH)_3$.
„ III. „ „ $HR(OH)H$. *e.g.* $HPO_3(OH)H$.

These examples will serve to show the suggestiveness of the results of thermal chemistry. Thomsen's three volumes teem with suggestions: his results throw light on such questions as are connoted by the expressions allotropy, molecular compounds, classification of elements and compounds, isomerism, and affinity.

It is in examining the subject of chemical affinity from the point of view of thermal chemistry that one becomes aware of the complexity of the problems included under this expression.

From the following numbers,

$[H, Cl] = 22{,}000 + ;\ [H, Br] = 8440 + ;\ [H, I] = 6050 - ;$

it might be concluded that the affinity of chlorine for hydrogen is much greater than that of bromine, and that the affinity of iodine for hydrogen is much less than that of bromine. But these thermal equations are not comparable; at ordinary temperatures chlorine is a gas, bromine a liquid, and iodine a solid; hence, on this ground alone, no precise conclusions can be drawn from the above data regarding the relative affinities for hydrogen of the three halogen elements. Again, looking at the numbers,

$$[C, O] = 28{,}600 + ;\ [C, O^2] = 97{,}000 +,$$

it might be said that when oxygen combines with carbon in quantities of 16 grams at a time, the union of the second parcel of 16 grams is attended with evolution of much more heat than accompanies the addition of the first parcel of 16 grams. But measurement of the heat of oxidation of carbon monoxide, $[CO, O] = 68{,}400 +$, at once negatives this conclusion, and rather points to the number 68,400 × 2 136,800 as representing the thermal value of the transaction, $C + O_2 = CO_2$, where C represents 12 grams of gaseous carbon.

In the ordinary chemical notation almost every chemical change is represented as much simpler than it really is; no indication is given of the fact that in most cases an *excess* of one or other of the reacting substances must be used. Thus the reaction usually written

$$\mathrm{AgCl} + \mathrm{HI}\ (\text{gas}) = \mathrm{AgI} + \mathrm{HCl}$$

would more correctly represent the distribution of the reacting bodies were it written

$$x\mathrm{AgCl} + x'\mathrm{HI} = x\mathrm{AgI} + x'\mathrm{HCl} + (x-1)\mathrm{AgCl} + (x-1)\mathrm{HI}.$$

If it is assumed that in the thermal study of a chemical reaction allowance is made for all the purely physical changes which accompany the chemical change, for the influence of the masses of the reacting substances and for the possible formation and decomposition of molecular groups during the reaction, there yet remains the consideration that heat is lost or gained to the system in the decompositions and formations of elementary molecules, which decompositions and recompositions may form parts of the entire change under examination. Thus, take the comparatively simple reaction

$$2\mathrm{H_2O} + \mathrm{Cl_4} = 4\mathrm{HCl} + \mathrm{O_2};$$

expanded thermally we have

$$r = 4[\mathrm{H, Cl}] + [\mathrm{O, O}] - 2[\mathrm{H^2, O}] + 2[\mathrm{Cl, Cl}].$$

Even the apparently most simple case, the union of two elements, is more complex than at first sight appears. $[\mathrm{H^2, Cl^2}] = 44{,}000 +$ simply tells that 2 grams of hydrogen combine with 71 grams of chlorine, and that 44,000 gram-units of heat are evolved. But if we wish to apply these data to questions concerning the affinity of chlorine for hydrogen, we must remember that affinity is the name given to the stress between atoms when regarded from the point of view of one kind of the reacting atoms. Hence, remembering that the molecules of hydrogen and chlorine are diatomic, we must amplify the equation $[\mathrm{H^2, Cl^2}] = 44{,}000 +$, and write it thus—

$$r = 2[\mathrm{H, Cl}] - [\mathrm{H, H}] - [\mathrm{Cl, Cl}] = 44{,}000 +;$$

but the value to be assigned to two of the terms in this equation are unknown. Until we are able to assign approximate values to the thermal changes accompanying the decompositions of elementary molecules and the combinations of elementary atoms, we shall not be in a position to apply thermal data to the subject of affinity, provided, that is, we use this term in its most precise meaning.

The statement of Berthelot in the "Essai de Mécanique Chimique," that the quantity of heat evolved in a reaction measures the sum of the physical and chemical changes which occur in that reaction, and furnishes a measure of the chemical affinities, is evidently untrue if we assign any precise meaning to the term "affinity." But if we use this term in a wide sense as summing up the various actions and reactions (other than those which are purely physical) which together constitute any given chemical change, then we may perhaps say that thermal measurements of comparable reactions are also relative measurements of the affinities of the reacting substances. It is in some such sense as this that the term "affinity" is used by Thomsen in his thermal researches on the relative affinities of the non-metallic elements (vol. ii.).

It is worthy of remark that Thomsen's arrangement of the commoner acids in order of relative affinities agrees very well with that given by Ostwald as the result of his investigations conducted on altogether different lines and by very different methods.

If thermal measurements of chemical changes really represent the sums of various partial changes, some of which have a positive and others a negative value, then it becomes doubtful whether any practical result is to be looked for from the application of Berthelot's *law of maximum work*, which runs thus:—

"Every chemical change, accomplished without the addition of energy from without the system, tends to the formation of that body or system of bodies the production of which is accompanied by evolution of the maximum quantity of heat."

Thomsen puts this "law" in a somewhat different form: he says, "Every simple or complex reaction of a purely chemical kind is accompanied by evolution of heat." Thomsen explains that by a purely chemical process he means one which is accomplished without addition of energy from sources external to the system, and consists in the "striving of atoms towards more stable equilibrium." But there are, I think, two principal objections to this statement. Actions "of a purely chemical kind," as thus defined, do not actually occur except as parts of cycles of reactions wherein are included changes not of a "purely chemical kind." And, secondly, we have at present no means of measuring the thermal values of those purely chemical actions—*i.e.* on Thomsen's view, atomic actions—but are obliged to include their values in the total value assigned to the complete cycle of operations which we term a chemical reaction.

Thomsen has it is true attempted to assign thermal values to the decomposition of the molecule of carbon into atoms and the recombination of atoms of carbon to form molecules. The pages of NATURE are scarcely suitable for a detailed discussion of Thomsen's methods; it seems to me, and I think to some others who have tried to follow Thomsen's arguments, both in the second volume of his "Untersuchungen" and also in the original papers in the *Berichte* and elsewhere, that these arguments really bristle with assumptions, and that a comparison of the results deduced by Thomsen with the actual calorimetric measurements obtained by himself and others is sufficient to throw grave doubt on the validity of those assumptions on which his arguments are based. One general result which appears to me to follow from Thomsen's investigation is that the time has come when we may with great advantage give up such expressions as "the carbon atom has four bonds," "such or such atoms are held by double links," and indeed the whole of that unscientific pseudo-dynamical nomenclature which has grown up around the vague and indefinable conception of *atomic bonds*.

There are many other points of interest in Thomsen's "Untersuchungen"; but I have said enough I trust to show the importance and the remarkable suggestiveness of these volumes; and also to establish the statement that the great advances of the future in chemistry are to be looked for, not so much in the domain of organic chemistry as in the application of the methods and generalisations of the science of matter and motion to the problems which we call chemical.

M. M. PATTISON MUIR

A SCIENTIFIC CATALOGUE

Bernard Quaritch's General Catalogue. Part II. Natural History and Science. Part III. Periodicals, Journals, and Transactions. (London: 1881-83.)

IN few instances that a political economist could hold up as an example is the function of the merchant in the processes of supply and demand so clearly and simply displayed as in that of Mr. Bernard Quaritch, the wealthy merchant in the book trade. He is especially a merchant-man seeking goodly pearls, whose great qualification must be that he knows the exact demand for, and the exact scarcity of, what is to be bought and sold. His catalogue does not aim at completeness as did the one which we noticed lately. Scarcely more than one-tenth of the titles carefully entered in Mr. Friedländer's lists are to be found here; but these make a collection, and a very large one, of books brought together by "natural" selection with the same good results in this case of intelligent working, as in the more automatic world around us. Many eminent men in various branches of science have first selected books bearing upon their own subjects, and then, on the dispersion of such libraries, Mr. Quaritch selects those works which have a higher value through their own superior merit, or the often doubtful though highly-prized recommendation of rarity. Accordingly Mr. Quaritch's catalogue is considerably like the sum total of British legislation. Each item of it was the supply of an existing want according to the best light of the time of its production. While circumstances, however, have changed and fresh laws have been devised to meet the changed circumstances, old laws have remained upon the statute book, and the existing code contains at the same time both inconsistent repetitions and grave deficiencies, and lacks both symmetry and completeness. While the catalogue of Mr. Friedländer shows the German love of both these good qualities and the scientific tastes of the compiler, that of Mr. Quaritch does not profess to be complete in any sense; it is a list of an immense stock of books brought together, as their former possessors ceased to require them, by a shrewd man of business who knew their market value. Hence in examining these bound up volumes which contain the many rich prizes of scientific literature constituting Part II. and Part III. of a new "General Catalogue," one is not surprised to find that a book like Agassiz's "Nomenclator Zoologicus" is to be found in four different places in one of them; that five copies of Owen's "Odontography" are offered, and a variety of copies of many others.

In Friedländer's catalogue we had to complain of too much classifying; not because classification is not of extreme value as a ready guide to the contents of a catalogue or library, but because many books refuse to fall under one head only, however discreet may be the arrangement. Mr. Bernard Quaritch's catalogue is just the reverse. In these volumes there is no attempt at either alphabetical or subject-divisions of the whole collection; different divisions are lists of books purchased at particular sales. A concise index makes up perhaps in the best way for this utter confusion of subjects. The table of contents, to which one would look first in trying to understand such a catalogue, is not printed in a way to clearly express the arrangement of those titles which *are* classified in subjects. A list of thirteen natural history headings follows "Egypt and North Africa" in exactly the same way as a nearly similar list of fourteen follows "The British Isles," but the former has nothing to do with Egypt as the latter had to do with the British Isles.

But Mr. Quaritch is the great connoisseur in a different class of books from the works which draw our attention in his catalogue. This class it would hardly come within our province to notice, were it not for the evidence given here, on the one hand, that costly books are purchased now as much as of old by the "patron" of literature, and on the other, that scientific works of original value and present scarcity are bought up by mere book collectors or bibliolaters, who would in many cases fret while one of their precious volumes was being turned over for consultation, lest it should end in a crack in its beautiful binding! Mr. Quaritch labours abundantly, and not without love, we think, for these purchasers. Here are a few of the feminine pomps and vanities with which he tickles the ears of bibliomaniacs:—"Grolier binding," "variegated leathers," "gold scroll tooling," "purple morocco super extra," "veau fauve," "veau marbré," "arms and cypher of ———," "vellum fly-leaves," "large paper," "tall copy," "magnificent specimen of bibliopegistic skill." Here is a titbit:—"First Aldine edition, very large, fine copy, in blue morocco, gold tooling, silk lining, vellum fly-leaves, gilt gaufré edges, by Bozerian."

A distinguishing feature in Mr. Quaritch's catalogues are the valuable notes appended to nearly all the most important of the works he offers. These notes as to the scarcity, completeness, market value, and often the history of the book testify to both the extent of his business and the minute accuracy of his knowledge of it. They are a mine of valuable information to any one whose business is in books, either commercially or as a librarian intrusted with the care and also the completion of important collections. In few cases will a book only professing to be a stock-list itself command a price in the market. Mr. Quaritch's catalogues command a high price, and the new edition of his general one, of which seven parts are now out, and which will probably not be completed for another year, if it should be the last which our veteran publishes, will doubtless remain for some time to come a standard work upon literature.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Elevation and Subsidence

FOR several months past articles and letters have appeared in NATURE on the subject of subsidence and elevation of the earth's crust by addition and removal of weight. In this connection also much has been said in regard to the history of the idea. I wish therefore to draw attention to the fact that in 1859 I read a paper before the American Association for the Advancement of Science on the subject of the "Formation of Continents and Ocean Basins," in which, after giving the views of Herschell and Airy, I bring out this idea very prominently, and illustrate it by many diagrams. An abstract of this paper, by Sterry Hunt, was published in the *Canadian Naturalist*, vol. iv., 1859, p. 293, and reference to it will be found in the "Royal Society Catalogue," vol. iii. p. 919.

A very brief outline of the paper is as follows:—I make two assumptions: (1) an internal liquid with floating crust; (2) the crust of continental areas more conductive and therefore cooling and thickening more rapidly than that of oceanic areas.

It is evident that under these assumptions inequalities would commence first on the under surface of the crust by additions there, making convexities beneath the continental and concavities beneath the oceanic areas. But by *flotation* these inequalities on the under side next the liquid would be reproduced on the upper side next the atmosphere, and by this means alone continents would grow continually higher, and ocean beds deeper. Now add to these erosion. By cutting down continents and filling up the seas erosion would tend constantly to destroy these inequalities, while flotation would tend as constantly to reproduce them. Thus according to this view the continents rise partly by additions beneath and partly by removal above, and similarly the ocean beds sink partly by increased concavity beneath and partly by additions above. But evidently if unequal thickening should stop, flotation could only *partly* restore the inequalities destroyed by erosion.

Except the abstract above referred to, the paper was never published, and in February, 1865, it was destroyed, along with much else, by Sherman's army. My reason for not publishing more fully was that I soon became dissatisfied with it; for about that time the views of Hopkins and Pratt on the solidity of the earth began to attract attention, and I became convinced that dynamical geology must be reconstructed on a basis of a solid earth. But now that the idea of a sub-crust liquid or semi-liquid layer is becoming prominent (a condition which would not probably interfere with the substantial solidity of the earth in its astronomical relations), it seemed to me important that this long forgotten paper should be brought forward merely as a part of the history of the subject.

Now a few words on the subject of the communications referred to in the beginning of this letter. It seems to me that some of your correspondents have gone too far in regarding unloading by erosion as a cause of elevation. Evidently there must be some other and more fundamental cause, or erosion could not act. Evidently erosion can only partly restore an elevation produced by some other cause. Erosion is primarily an effect of elevation, only in this as in so many other cases the effect may react as a cause, to maintain the elevation. For example, the Colorado plateau region has been raised since Cretaceous times about 20,000 feet, but the maximum general erosion has been only about 12,000 feet. The erosion has been, therefore, the consequence, not the cause, of elevation, for it is impossible that the cause should lie so far behind the effect. I give this one example because it is on so large a scale, but every mountain range furnishes an example of great erosion as an effect of elevation produced by other causes. That loading and unloading the crust is a cause of subsidence and elevation there is little doubt, but that there are other and far more important causes is certain.

Berkeley, Cal., December 3 JOSEPH LECONTE

Red-deer Horns

IN continuation of my remarks on the eating of shed deer-horns by other deer, I have to add that six shed horns in various stages of erosion have been sent to me from Sutherlandshire. They each bear well defined teeth-marks on the gnawed portions, and this leaves little if any doubt that the popular belief that the horns are eaten by deer is founded on fact. The accompanying interesting letter from Mr. James Inglis, which gives the evidence of two experienced stalkers, both most intelligent and reliable men, is further confirmation of a curious though no doubt very natural habit of the deer, which finds in the lime-salts of the horn a necessary element of nutrition. You will observe that Inglis believes the deer use the molars in eating the bone, and this seems probable enough, as they apparently always begin at the points and eat towards the beam and burr, a method of proceeding by which they can bring portions of the horn within the action of the molars. J. FAYRER

December 27, 1883

"... I send a few red-deer horns that have been partially gnawed by deer in the forest. I asked the stalkers to keep a look out and see if they could find any deer eating horns, and am glad to say that they have been able to put the matter beyond all doubt.

"Donald McRae saw with his glass a stag, in Dunrobin Glen, eating a horn; he went to the place where he saw him eating it, and found it partially eaten. I send it with the others. You will find a ticket on it to distinguish it from the rest.

"Duncan McPherson saw with his glass a hind, last week, eating a horn also; he did not find the horn, but he saw her (the hind), quite plainly, with it in her mouth, gnawing away at it near the point.

"Deer have no incisors in the upper jaw, but they have grinders or molars in both upper and lower jaws, formidable enough to eat any horn, and I have no doubt that it is with their molars that the horns are eaten.

"A shepherd in the parish of Lairg has a cow that eats all the bones she can find, and goes miles for them, and eats them up, shank bones and all; ribs are eaten easily, and seem to give no trouble whatever. "JAMES INGLIS

"December 24, 1883"

On the Absence of Earthworms from the Prairies of the Canadian North-West

NOT by any means the least remarkable of the very notable series of works which Mr. Darwin has given to the world is that which came last from his pen but a short time previous to his lamented death. Dealing, as it does, with effects which, when looked at in the detail, are exceedingly small and insignificant, but, when viewed in the aggregate, are shown to be of surprising importance, the "Vegetable Mould and Earthworms" must certainly rank as a most strikingly interesting work.

It is not my desire to call in question the conclusions at which Mr. Darwin has arrived with regard to the action of earthworms in cultivating the soil, but I wish to point out that in one extensive portion of the earth's surface, to which much attention has of late been directed on account of its agricultural capabilities, earthworms do not exist. I refer to the vast region commonly known as Manitoba and North-West Territories. My friend, Mr. E. E. T. Seton, of Carberry, Manitoba, was the first to point out to me that this enormous country must be regarded as forming an exception to Mr. Darwin's generalisations, on account of the total absence from it of every kind of earthworm, and, having lately returned from a visit to these regions, I can add my testimony to his in this particular, as well as in the matter of the amazing, innate fertility of the soil, which has been the wonder and remark of all travellers for years past, but which, in this case, obviously cannot be attributed to the action of worms, since these do not exist there. In addition to my own observations, I have the testimony of numbers of intelligent settlers, most of whom had been several years in the country, but all of whom unhesitatingly assured me that such a thing as an earthworm was unknown. Further, Mr. Leo Rogers, son of Mr. Thos. Rogers of Manchester, who has spent several years with the engineers of the Canadian Pacific Railway, has informed me that earthworms are unknown between Winnipeg and the Rockies. This being the case, it does not seem reasonable to suppose that they exist anywhere in the huge territory still further to the north, and comprising upwards of 3,000,000 square miles of land, or something like one third of the entire North American continent, and which may therefore be regarded as forming an exception to Mr. Darwin's statement (p. 120), that "Worms are found in all parts of the world, and some of the genera have an enormous range. They inhabit the most isolated islands; they abound in Iceland, and are known to exist in the West Indies, St. Helena, Madagascar, New Caledonia, and Tahiti. In the Antarctic regions worms from Kerguelen Land have been described by Ray Lankester, and I have found them in the Falkland Islands. How they reach such isolated spots is at present quite unknown." In connection with the statement (p. 121) that "Worms throw up plenty of castings in the United States," it may be pointed out that the boundary line (the 49th parallel) is to some extent a natural one, from which the rivers run both north and south. Further, I have been assured by friends, and have also seen with my own eyes, that earthworms abound at Toronto and in other parts of Ontario. This being the case, an interesting inquiry arises as to the cause of the absence of worms from the North-West, and I can only suggest two probable reasons—the great cold of winter and the prevalence of prairie fires in spring and autumn. Personally I favour the latter, though both causes may in part be answerable. If worms abound in Iceland (65° N. lat.), in Kerguelen Land (50° S. lat.), and in Toronto (43·4° N. lat., mean winter temperature 27¼° F.), why should they not also occur at Winnipeg (50° N. lat.)? Certainly the mean winter temperature is very low, being about 8° F., and the mean minimum for eleven years − 40½° F. I made special inquiries as to the depth to which the soil in Manitoba becomes frozen in winter. This is often as much as five or six feet, but only, I believe, in the more exposed places, and certainly as a rule it is thawed again in the spring. I do not think this would render the ground uninhabitable by worms when they are able to exist in Iceland. Mr. Darwin says nothing as to the effect of frost on worms except (p. 26) that "worms are sensitive to a low temperature, as may be inferred from their not coming out of their burrows during a frost"; but he states (p. 110) that they are easily able to descend three or four or even seven or eight feet below the surface. It would be interesting to ascertain whether worms inhabit equally cold portions of the Old World.

But the agency which I believe has caused the absence of earthworms from the North-West is, as already stated, the prairie fires which annually sweep over enormous portions of the country, totally consuming the grass, and converting it into a black ash. This, it might well be imagined, would for months together completely deprive any worms that formerly existed of that variety of decaying vegetable matter that composes their food; and assuming that fires have annually passed over large portions of the prairies for scores of generations (as seems in every way probable), it appears to me only reasonable to suppose that this cause would effectually have exterminated the worms from the country or have prevented them occupying it. It is my belief (as I shall elsewhere state more fully) that the very fertile, fine, black, powdery, and almost soot-like soil from one to three feet thick, even the open, treeless nature of the prairies themselves, and the absence from their surface, so far as my observation goes, of every single species of mollusk, while many species abound in all the ponds, lakes, and streams, are all in a large degree, if not entirely, due to the action of the fire. If this view ultimately turns out to be correct, it will be further seen that the very means which has deprived the soil of the North-West of that natural cultivation which the soils of most other countries enjoy has, at the same time, liberally supplied it with a manure resulting from the charred ashes of the grass which is annually burned. My friend, Mr. T. Rogers, who has taken much interest in the absence of worms from the North-West, and is inclined to attribute it rather to frost than to fire, though he suggests that the "alkali" may possibly have had something to do with it, has already brought the subject before the Literary and Scientific Society of Manchester, where he seems to have met with a good deal of incredulity.

As another evidence of the absence of worms, the numerous, large, Glacial boulders that strew the prairies around Brandon and elsewhere may be cited. These, had worms existed, would doubtless have long ago been lowered beneath the surface, as also the skulls and other bones of buffaloes, which so abound on the prairies, and most of which have evidently lain there a long while. Nevertheless some of these have been buried in the course of time, as one gentleman told me that he had sometimes turned them up from a depth of two or three inches beneath the surface when ploughing. Their burial may have been accomplished by the wind drifting soil over them, or by the working of gophers. Of these peculiar little animals two species are very abundant on the prairies, where they make extensive burrows, which it seems possible may to some extent accomplish the natural cultivation of the soil in the way worms are accustomed to do it elsewhere. Some more suggestive remarks on this point may be found in a paper by Mr. Seton, published in the Report of the Manitoba Department of Agriculture for 1882, and which may be studied with advantage. Chignal St. James, near Chelmsford, December 20, 1883

Magnetic Dip in South China and Formosa

WHILE engaged on a meteorological mission in China I availed myself of the opportunity to make the following determinations of the magnetic dip. The observations in Hong Kong were made at the public gardens, the Observatory being not yet ready. On October 10 I observed at the British Consulate; on November 3 at the English Presbyterian Missions Compound, Swatow. In Amoy I observed at the residence of the Commissioner I.M. Customs, in Takow (Formosa) at the Custom House, and at the South Cape (Formosa), near the magnificent fortified lighthouse. It is to be feared that the observations on the coast of China are slightly vitiated from local attraction, the rocks consisting of ferruginous granite. Southern Formosa is built up of coral, raised in places to a great height, no doubt through volcanic action. Slight earthquakes are of common occurrence in Formosa, whereas along the coast of China they are rare and of no importance except to the seismologist.

Hong Kong, Nov. 10

THE ORIGIN OF CORAL REEFS

REGARDING this interesting geological problem, which has recently been discussed in NATURE, we are enabled through the kindness of Mr. Murray, of the *Challenger* Commission, to publish a letter which has been addressed to him by Dr. Guppy from the Pacific. The importance of this communication will be recognised in the confirmation it supplies of the inference that coral reefs start upon a platform of limestone composed of the remains of foraminifera, &c., and are themselves of no great thickness. Dr. Guppy will no doubt continue his researches, and we may hope to obtain from him precise data regarding the average thickness of the coral rock, the lithological difference between it and the underlying limestone, the structure of the limestone, whether any succession of organisms can be detected in it, and whether at any point the underlying volcanic rock can be seen which would afford a measurement of the thickness of the calcareous deposits. The effects of denudation and their relation to height above the sea will no doubt also receive his attention.

"*Shortlands Islands, Solomon Group,*
"*August* 7, 1883

"During the twelve months I have spent in this group of islands—serving as surgeon on board H.M. surveying-ship *Lark*—I have been much interested in and have devoted considerable attention to the raised coral formations in various islands; and as my observations may be of service towards confirming the views which you have advanced with reference to coral islands and reefs, I will state briefly the results of my observations.

"Excluding the large continental islands, I will refer for the sake of brevity to the numerous small islands of this archipelago, those of volcanic, and those of calcareous formations. Confining myself to the islands of calcareous formation, I will pass over the numerous small islands which are entirely composed of coral detritus, sand, and shells, and have been formed by the materials thrown up by the waves at the present sea-level; and will restrict my remarks to a very common type of islands in this group, with gently sloping and rounded profile, having an elevation varying perhaps between 100 and 1100 or 1200 feet, and composed in bulk of *an impure earthy or argillaceous limestone*, usually bedded, and almost always *foraminiferous*, now and then rich in other pelagic organisms, such as *Pteropods*. On this rock *rests the* *coral limestone*, which forms but a comparatively thin crust, and has been altogether removed from most of the higher regions by sub-aërial agencies. However, I have observed the raised coral rock still preserved at considerable heights above the sea, and in two localities at elevations of 900 feet.

"Amongst the sub-group known as the Shortland Islands, I came upon beds of this *impure calcareous rock* (beneath the raised coral rock) *abounding in Pteropods*, mostly *Hyalæa*, and large foraminiferous tests, mingled with shells, some of them of shallow water habit.

"I am, &c., "H. B. Guppy"

A FORGOTTEN EVOLUTIONIST

A BOOK has lately come into my hands a few words about which may possibly interest some of the readers of NATURE. Its title is "Histoire Naturelle des Fraisiers"; the author was A. N. Duchesne, and it was published at Paris in 1766. It must be, I suspect, an uncommon book, for there is no copy in the library of the Royal Gardens at Kew. And this library, comprising as it does the contributions of many collectors who allowed little to escape them, is remarkably complete; Mr. Daydon Jackson has in fact found in it more than a thousand publications the titles of which are not to be met with in the last edition of Pritzel's well-known "Thesaurus."

The scarceness of a botanical book is not perhaps in itself a matter of any great moment, and I bought the book out of a provincial sale catalogue without expecting it to be particularly interesting, though I knew Duchesne's name as an authority on the cultivated forms of the strawberry. I very soon, however, came to the conclusion on looking over it that it was a very remarkable production indeed, and in a scientific sense at least a century in advance of its time.

Duchesne's book is in fact the record of a purely biological study of a small group of plants. The significance of work of this sort has only been thoroughly recognised since the publication of the "Origin of Species." Just as with C. K. Sprengel, whose book was also written in the last century (1793), the world has had to roll on far into another hundred years before it was ready to do justice to this kind of research. There is a curious incongruousness between the freshness and modernness of the ideas and the faded type and musty paper in which they are embalmed.

Duchesne plunges at once into the business of his book in the first line of the preface with a straightforward simplicity not unworthy of Mr. Darwin. I will attempt a translation of the first paragraph:—

"The wish to see if it were possible to raise from seed a plant which scarcely ever produces any has led me by a happy chance to the production of a new race, which made its appearance at Versailles in 1761. This circumstance induced me to more closely devote myself to the study of strawberries, and led me to another discovery. I found that they are not all truly hermaphrodite; forms exist, in fact, which are sexually differentiated.[1] And I have succeeded in the past year, 1765, in fertilising, by means of one set of plants, individuals of another sort, which are cultivated as a matter of curiosity, and are constantly sterile. One, amongst others, has produced fruits of great beauty; M. le Marquis de Marigny has obtained for me the honour of having this submitted to the king, and it is to be raised in the Versailles Gardens by my method. This unexpected success has still more redoubled my ardour to make further observations."

The race so produced, which Duchesne called *Le Fraisier de Versailles*, or *Fragaria monophylla*, is undoubtedly a very curious plant. All its leaves are permanently unifoliate; *i.e.* instead of bearing three leaflets, as is ordinarily the case with strawberries, the petioles bear but one. Duchesne observes that this is also the case with the first leaves of all seedling strawberries. *Fragaria monophylla* may be therefore regarded as a form which always retains the juvenile, and never arrives at the adult, foliage, and this peculiarity remains constant in subsequent generations. The effect of crossing, as a potent stimulus to variation, could not but have powerfully impressed Duchesne in so striking a case as this, and further observations seemed to have led him to account for the common characters which otherwise diverging forms exhibited as best accounted for by a common ancestral origin. The study of geographically separated species, however, necessarily led him to see that something more than crossing was needed to account for variation in every case. In discussing *Fragaria virginiana*, a native of North America, which is the origin of the race of Scarlets, Duchesne speculates as to its derivation from the wild *F. vesca* of Europe, and attributes the divergences from this type to the effect of North American soil and climate.

His work on Strawberries, where he was dealing mainly with races, led him to speculate with regard to the higher groups of species, genera, and orders. His results seem to me, for the time, so extraordinarily bold, and therefore historically so interesting, that I quote the first portion of the Recapitulation, pp. 219-221, entire, in the original French:—

"J'ai déjà dit, à l'occasion du Fraisier-ananas, qu'il étoit très-difficile de ranger en ligne droite les diverses Races d'une même Espèce, de manière qu'on pût passer de l'une a l'autre par gradations de nuance. Cela est peut-être aussi impossible, que de ranger en ligne droite les Espèces, les Genres, et les Familles; par la raison que chaque Race, comme chaque Espèce, chaque Genre, ou chaque Famille, a des rapports de ressemblance avec plusieurs autres.

"L'ordre Généalogique est donc le seul que la nature indique, le seul qui satisfasse pleinement l'esprit; tout autre est arbitraire et vide d'idées. J'ai eu soin, à chacune des Races de Fraisiers, d'indiquer ce qui m'a paru vraisemblable à cet égard; mais je n'ose me flatter d'avoir toujours rencontré juste. Il faudroit, pour le bien faire, avoir des connaissances certaines et précises du pays natal de chaque Fraisier, ou bien, du tems où il a été élevé de graine, et de quel autre Fraisier provenoit cette graine; j'ai fait voir combien on manquoit encore de lumières sur tout cela.

"C'est par cette raison que je me suis permis de donner mes conjectures; en voici les résultats; la forme d'Arbre généalogique les rendra encore plus sensibles, et en fera mieux saisir l'ensemble."

It is certainly startling to come upon a phylogeny of the most modern type in a book more than a century old.

It was not till after I had gratified myself with a study of Duchesne's remarkable speculations that it flashed across my mind that attention had already recently been called to them; and I found, in fact, that Prof. Alphonse de Candolle, in a short paper put together with the felicitous erudition of which he seems to possess so inexhaustible a store, had already, in May of last year,[1] stated most of the points on which I have dwelt above. And he mentions that, on the occasion of a visit to Mr. Darwin in 1880 he told him of the existence of the book, which he describes, justly enough, as "a very curious work, older than that of Lamarck, but to which no one had ever referred except for points of secondary interest."

I know little about Duchesne himself. De Candolle says that he was a horticulturist and Professor of Natural History, and that his knowledge was as varied as it was sound. No one, nevertheless, ever seems to have paid the smallest attention to his evolutionary theories. Even Silvestre, who pronounced his *éloge* at a public meeting of the Société Royale d'Agriculture in 1827, abstains from the slightest reference to them.

---

[1] This must be one of the first observations of the tendency of plants with hermaphrodite flowers to pass into the diœcious state. The fact is now well established. (See Darwin's "Forms of Flowers," pp. 278-309.)

[1] "Darwin considéré au point de vue des causes de son succès," &c., *Archives des Sciences*, May, 1882.

While in his experiments and his mode of drawing conclusions from them Duchesne strongly recalls the method of Mr. Darwin, the parallel cannot be carried further. In so far as he obtained a glimpse at the modern doctrine of evolution it was in the form afterwards formulated by Lamarck. Of the part played by the struggle for existence in the matter I find no trace in his writings. W. T. THISELTON DYER

TEACHING ANIMALS TO CONVERSE

MR. DARWIN'S notes on Instinct, recently published by my friend Mr. Romanes, have again called our attention to the interesting subject of instinct in animals.

Miss Martineau once remarked that, considering how long we have lived in close association with animals, it is astonishing how little we know about them, and especially about their mental condition. This applies with especial force to our domestic animals, and above all of course to dogs.

I believe that it arises very much from the fact that hitherto we have tried to teach animals rather than to learn from them,—to convey our ideas to them, rather than to devise any language, or code of signals, by means of which they might communicate theirs to us. No doubt the former process is interesting and instructive, but it does not carry us very far.

Under these circumstances it has occurred to me whether some such system as that followed with deaf-mutes, especially by Dr. Howe with Laura Bridgman, might not prove very instructive if adapted to the case of dogs.

Accordingly I prepared some pieces of stout cardboard, and printed on each in legible letters a word such as "Food," "Bone," "Out," &c. The head master of one of the deaf and dumb schools kindly agreed to assist me. We each began with a terrier puppy, but neither of us obtained any satisfactory results. My dog indeed was lost before I had had him long. I then began training a black poodle, "Van" by name, kindly given me by my friend Mr. Nickalls. I commenced by giving the dog food in a saucer, over which I laid the card on which was the word "Food," placing also by the side an empty saucer, covered by a plain card.

"Van" soon learnt to distinguish between the two, and the next stage was to teach him to bring me the card; this he now does, and hands it to me quite prettily, and I then give him a bone, or a little food, or take him out, according to the card brought. He still brings sometimes a plain card, in which case I point out his error, and he then takes it back and changes it. This however does not often happen. Yesterday morning, for instance, "Van" brought me the card with "Food" on it, nine times in succession, selecting it from among other plain cards, though I changed the relative position every time.

No one who sees him can doubt that he understands the act of bringing the card with the word "Food" on it as a request for something to eat, and that he distinguishes between it and a plain card. I also believe that he distinguishes for instance between the card with the word "Food" on it and the card with "Out" on it.

This then seems to open up a method, which may be carried much further, for it is obvious that the cards may be multiplied, and the dog thus enabled to communicate freely with us. I have as yet, I know, made only a very small beginning, and hope to carry the experiment much further, but my object in sending this communication is twofold. In the first place I trust that some of the readers of NATURE may be able and willing to suggest extensions and improvements of the idea.

Secondly, my spare time is small and liable to many interruptions; animals also we know differ greatly from one another. Now many of your readers have favourite dogs, and I would express a hope that some of them may be disposed to study them in the manner indicated.

The observations, even though negative, would be interesting; but I confess I hope that some positive results might follow, which would enable us to obtain a more correct insight into the minds of animals than we have yet acquired. JOHN LUBBOCK

High Elms, Down, Kent, December 20, 1883

THE FRENCH DEEP-SEA EXPEDITION OF 1883

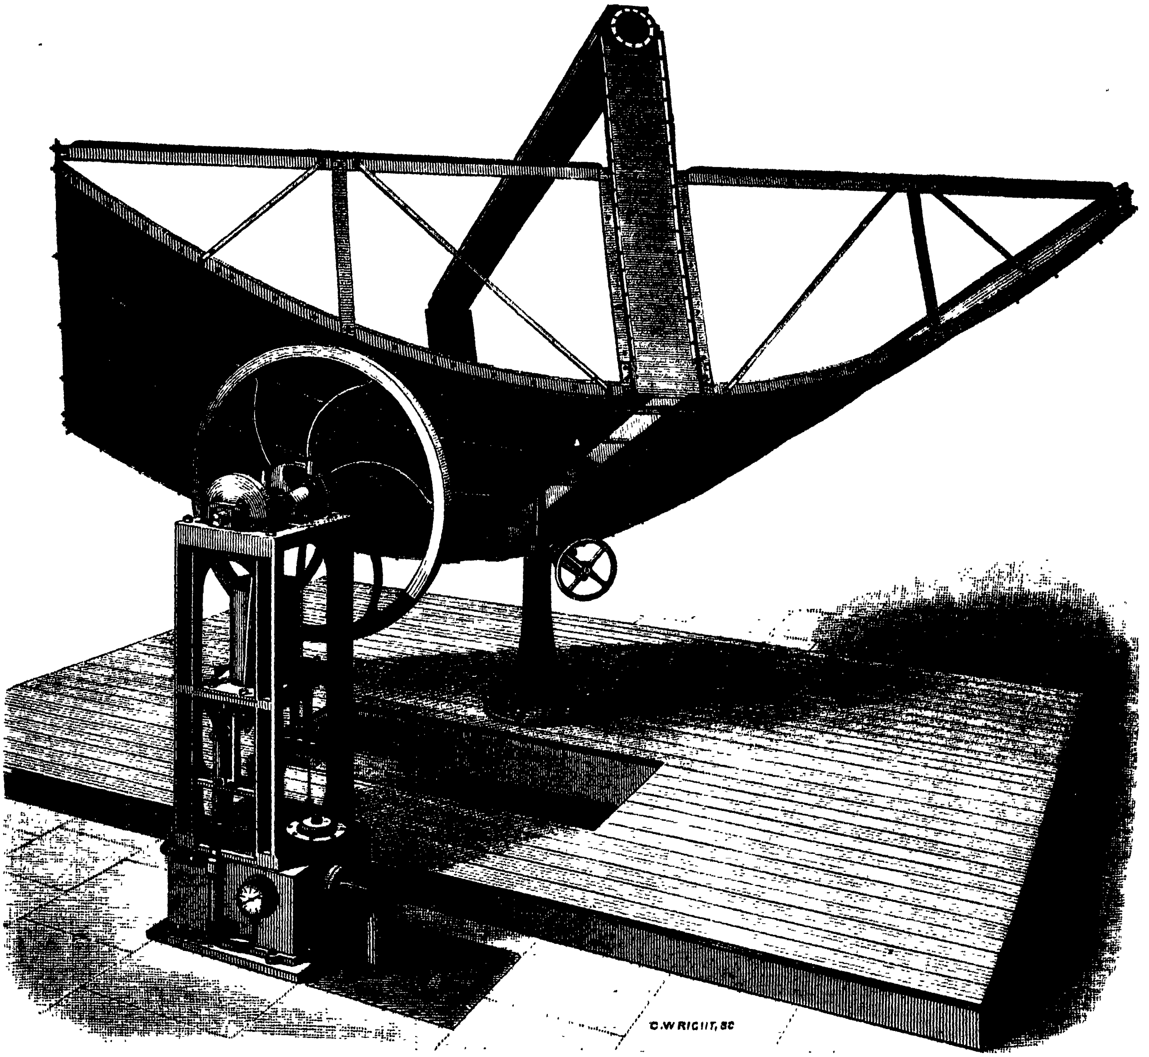
I HAVE just returned from a very short visit to Paris, made for the purpose of inspecting the Mollusca which were procured during last summer's deep-sea expedition in the French Government steamer *Talisman.* The expedition was under the scientific charge of Prof. Alphonse Milne-Edwards. For the opportunity of this inspection I was indebted to the kindness of my friend Dr. Paul Fischer, whose reputation as a conchologist is so well known.

The course of the expedition was along the Atlantic coasts of Spain, Marocco, Sahara, Senegal, Cape Verde Isles, the Canaries, and Azores; and the time occupied was three months. More full and accurate particulars will very shortly be given by Prof. A. Milne-Edwards to the Academy of Sciences, and be published in their *Comptes Rendus.* The collection will be exhibited next month to public view. The greatest depth explored was about 2200 fathoms. The trawl was mostly used. Life was plentiful everywhere. As was the case in the *Porcupine*, *Challenger*, and other expeditions of the same kind, many animals (especially Crustacea) at the greatest depths were highly and brightly coloured, some of them having large eyes, and others being blind or eyeless. There was an abundance of hitherto unknown forms (genera and species) in every department of zoology—fishes, Mollusca, Polyzoa, Crustacea, Annelids, Echinoderms, Polyps, Corals, Foraminifera, and Sponges Among the Mollusca were some remarkable cases of the wide distribution of species in respect of space as well as of depth. For instance, boreal shells, such as *Fusus islandicus* and *F. berniciensis,* which inhabit northern seas at moderate depths, viz. 50 to 80 fathoms, were found living off the coast of Marocco, and the latter species even below the tropic of Capricorn, at depths of from 450 to 2200 fathoms. *Lima excavata,* considered a peculiarly Norwegian species, was likewise obtained off the Moorish coast, of a very large size; it was recorded by Prof. Seguenza as a Pliocene fossil of Sicily and Calabria, under the name of *Lima gigantea.* In the *Porcupine* Expedition of 1870 fragments were dredged off Cape St. Vincent; and in the *Challenger* Expedition this fine species was obtained from 10 to 175 fathoms off Western Patagonia and Japan. A bivalve (*Scrobicularia longicallus*), which in northern seas inhabits moderate depths, was procured in many places by the *Talisman*, at depths varying from 350 to 1429 fathoms. It occurred living in the deepest dredgings of the *Porcupine* Expedition of 1869, off the coast of Brittany, at a depth of 2435 fathoms. Many Mollusca (*e.g. Pecten vitreus*, *Limopsis minuta*, *Dentalium agile*, *Trochus ottoi*, *Columbella haliæeti*, and *Scaphander punctostriatus*) seem to inhabit the depths of the North Atlantic in every part, from one side to the other. The smaller shells in the *Talisman* collection have not yet been picked out. The Marquis de Folin will, with his usual care and industry, undertake that part of the work, which will occupy some time; he has requested me to examine and name those species which are known to me. I understand that another deep-sea expedition will be made by our enterprising neighbours next summer, being the fourth in consecutive years.[1]

December 21, 1883 J. GWYN JEFFREYS

THE SUN MOTOR AND THE SUN'S TEMPERATURE

The annexed illustration (Fig. 1) represents a perspective view of a sun motor constructed by the writer, and put in operation last summer. This mechanical device for utilising the sun's radiant heat is the result of experiments conducted during a series of twenty years; a succession of experimental machines of similar general design, but varying in detail, having been built during that period. The leading feature of the sun motor is that of concentrating the radiant heat by means of a rectangular trough having a curved bottom lined on the inside with polished plates so arranged that they reflect the sun's rays towards a cylindrical heater placed longitudinally above the trough. This heater, it is scarcely necessary to state, contains the acting medium, steam or air, employed to transfer the solar energy to the motor; the transfer being effected by means of cylinders provided with pistons and valves resembling those of motive engines of the ordinary type. Practical engineers as well as scientists have demonstrated that solar energy cannot be rendered available for producing motive power, in consequence of the feebleness of solar radiation. The great cost of large reflectors and the difficulty of producing accurate curvature on a large scale, besides the great amount of labour called for in preventing the polished surface from becoming tarnished, are objections which have been supposed to render direct solar energy practically useless for producing mechanical power.



Ericsson's Sun Motor, erected at New York, 1883.

The device under consideration overcomes the stated objections by very simple means, as will be seen by the following description:—The bottom of the rectangular trough consists of straight wooden staves, supported by iron ribs of parabolic curvature secured to the sides of the trough. On these staves the reflecting plates, consisting of flat window glass silvered on the under side, are fastened. It will be readily understood that the method thus adopted for concentrating the radiant heat does not call for a structure of great accuracy, provided the wooden staves are secured to the iron ribs in such a position that the silvered plates attached to the same reflect the solar rays towards the heater. Fig. 2 represents a transverse section of the latter, part of the bottom of the trough, and sections of the reflecting plates; the direct and reflected solar rays being indicated by vertical and diagonal lines.

---

[1] P.S.—In NATURE of December 20 (p. 172), I overlooked the misprint of India for Sweden.—J. G. J.

Referring to the illustration, it will be seen that the trough, 11 feet long, and 16 feet broad, including a parallel opening in the bottom, 12 inches wide, is sustained by a light truss attached to each end; the heater being supported by vertical plates secured to the truss. The heater is 6¼ inches in diameter, 11 feet long, exposing $130 \times 9{\cdot}8 = 1274$ superficial inches to the action of the reflected solar rays. The reflecting plates, each 3 inches wide and 26 inches long, intercept a sunbeam of $130 \times 180 = 23{,}400$ square inches section. The trough is supported by a central pivot, round which it revolves. The change of inclination is effected by means of a horizontal axle—concealed by the trough—the entire mass being so accurately balanced that a pull of five pounds applied at the extremity enables a person to change the inclination or cause the whole to revolve. A single revolution of the motive engine develops more power than needed to turn the trough, and regulate its inclination so as to face the sun, during a day's operation.

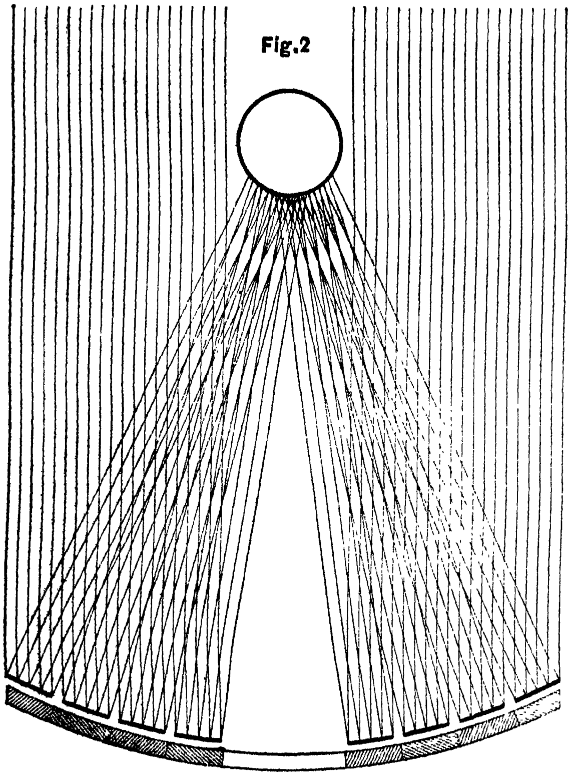


Fig. 2

The motor shown by the illustration is a steam-engine, the working cylinder being 6 inches in diameter, with 8 inches stroke. The piston rod, passing through the bottom of the cylinder, operates a force-pump of 5 inches diameter. By means of an ordinary cross-head secured to the piston-rod below the steam cylinder, and by ordinary connecting rods, motion is imparted to a crank shaft and fly-wheel applied at the top of the engine frame; the object of this arrangement being that of showing the capability of the engine to work either pumps or mills. It should be noticed that the flexible steam-pipe employed to convey the steam to the engine, as well as the steam chamber attached to the upper end of the heater, have been excluded in the illustration. The average speed of the engine during the trials last summer was 120 turns per minute, the absolute pressure on the working piston being 35 lbs. per square inch. The steam was worked expansively in the ratio of 1 to 3, with a nearly perfect vacuum kept up in the condenser inclosed in the pedestal which supports the engine frame.

In view of the foregoing, experts need not be told that the sun motor can be carried out on a sufficient scale to benefit very materially the sun-burnt regions of our planet.

With reference to solar temperature, the power developed by the sun motor establishes relations between diffusion and energy of solar radiation which show that Newton's estimate of solar temperature must be accepted. The following demonstration, based on the foregoing particulars, will be readily comprehended.

The area of a sphere whose radius is equal to the earth's mean distance from the sun being to the area of the latter as $214{\cdot}5^2 : 1$, while the reflector of the solar motor intercepts a sunbeam of 23,400 square inches section, it follows that the reflector will receive the heat developed by $\frac{23400}{214{\cdot}5^2} = 0{\cdot}508$ square inch of the solar surface. Hence, as the heater of the motor contains 1274 square inches, we establish the fact that the reflected solar rays acting on the same are *diffused* in the ratio of $1274 : 0{\cdot}508 = 2507 : 1$. Practice has now shown that, notwithstanding this extreme diffusion, the radiant energy transmitted to the reflector by the sun is capable of imparting a temperature to the heater of 520° Fahr. above that of the atmosphere. The practical demonstration thus furnished by the sun motor enables us to determine with sufficient exactness the minimum temperature of the solar surface. It also enables us to prove that the calculations made by certain French scientists indicating that solar temperature does not exceed the temperatures produced in the laboratory are wholly erroneous. Had Pouillet known that solar radiation, after suffering a *two-thousand-five-hundred-and-seven-fold* diffusion, retains a radiant energy of 520° Fahr., he would not have asserted that the temperature of the solar surface is 1760° C. Accepting Newton's law that "the temperature is as the density of the rays," the temperature imparted to the heater of the sun motor proves that the temperature of the solar surface cannot be less than $520° \times 2507 = 1{,}303{,}640°$ Fahr. Let us bear in mind that, while attempts have been made to establish a much lower temperature than Newton's estimate, no demonstration whatever has yet been produced tending to *prove* that the said law is unsound. On the contrary, the most careful investigations show that the temperature produced by radiant heat emanating from incandescent spherical bodies diminishes inversely as the *diffusion* of the heat rays. Again, the writer has proved by his vacuum-actinometer, inclosed in a vessel maintained at a constant temperature during the observations, that for equal zenith distance the intensity of solar radiation at midsummer is 5°·88 Fahr. less than during the winter solstice. This diminution of the sun's radiant heat in aphelion, it will be found, corresponds within 0°·40 of the temperature which Newton's law demands. It is proposed to discuss this branch of the subject more fully on a future occasion.

The operation of the sun motor, it will be well to add, furnishes another proof in support of Newton's assumption that the energy increases as the *density* of the rays. The foregoing explanation concerning the reflection of the rays (see Fig. 2), shows that no augmentation of temperature takes place during their transmission from the reflector to the heater. Yet we find that an increase of the number of reflecting plates increases proportionably the power of the motor. Considering that the parallelism of the rays absolutely prevents augmentation of temperature during the transmission, it will be asked: What causes the observed increase of mechanical power? Obviously, the energy produced by the increased *density* of the rays acting on the heater. The truth of the Newtonian doctrine, that the energy increases as the density of the rays, has thus been verified by a practical test which cannot be questioned. It is scarcely necessary to observe that our computation of temperature—1,303,640° Fahr.—does not show maximum solar intensity, the following points, besides atmospheric absorption, not having been considered:—(1) The diminution of energy attending the passage of the heat rays through the substance of the reflecting plates; (2) the diminution consequent on the great amount of heat radiated by the blackened surface of the heater; (3) the diminution of temperature in the heater caused by convection.

J. ERICSSON

A CHRISTMAS VISIT TO BEN NEVIS OBSERVATORY

ALTHOUGH I have no tale of perilous adventure or hair-breadth escape to tell the readers of NATURE, yet I think that they will be interested to hear of the progress that is being made in the first British attempt at the cultivation of high-level meteorology. This interest will be all the greater that the hearty encouragement and support that the Ben Nevis experiment has received from all parts of the United Kingdom has given it the character of a national undertaking.

As most of the readers of NATURE doubtless know, the observatory is at present in the experimental stage. A good road to the top with bridges and waterways has been made, and a part of the building erected sufficient to shelter the observers. It was judged wise to build as little as possible, until experience should have taught us the peculiar difficulties to be contended with in the somewhat novel circumstances presented by the summit of Ben Nevis in winter time. For, although several high level meteorological observatories, and indeed many other human habitations, already exist at much greater heights above the sea, yet there is probably no spot at present inhabited all the year round that presents climatic vicissitudes so remarkable. When winter is over, the directors will have a full report, with practical suggestions from the superintendent, Mr. Omond, to guide them in their further operations. Still it was thought well that some of the governing body should see with their own eyes the state of the observatory, and the work of the observers during the cold season. Accordingly two of them (Mr. John Murray and myself) made a visit of inspection on December 26th, of which I propose to give a few particulars.

Accompanied by Mr. Maclean, the contractor for the road and observatory buildings, we started from Fort William about 9.30 on Wednesday morning. At first the sky was dark and gloomy, and it was thought that Ben Nevis was to give a specimen of his worst weather. It was not cold however; in fact it was oppressively warm during the first thousand feet of the ascent from the farm of Achantie where the new road begins. This, coupled with the fact that the pony which one of the party rode up the first 2500 feet of the hill somewhat forced the pace, made it a little uncomfortable for the two pedestrians. The newly made road, loosened by the frost, and sodden by the rain and melting snow, was in places very heavy. Up as far as the little lake (Loch an Meall aut Suidhe), however, the roadway had suffered no substantial damage, except that the fall of a large stone had carried away a small piece of the margin; and all the bridges and waterways were found in excellent condition. This is very satisfactory, for the snow has already been down to Fort William; and recently a very rapid thaw has carried it so completely away, that on the 26th very little was met with under 3000 feet. The test has thus been tolerably severe and yet up to 2600 feet or so the road on the 26th was in far better condition than it was on the day of the opening ceremony. About the altitude just mentioned, a part of the road had been badly ploughed up by a spate of water from the melting snow; higher up still, the damage seemed to be less, but it was not so easy to judge, as the roadway was there gradually lost in the overlying snow.

As the party rose in height, the temperature of the air and the ardour of the pony alike fell, and then the walkers were left to the full enjoyment of their climb. During the latter part of the first 3000 feet, the mist had been so thick that the pony and its rider could scarcely be discerned a few yards off; but several hundred feet higher, after the road had been finally lost sight of in the snow, and all the party were on foot, we suddenly emerged about noon from the gloom of the mist into the brightest of daylight. Overhead the sky was blue, a fresh light breeze was blowing, and the reflected sunlight was shining in silvery masses on the undulating surface of the frozen snow. We soon reached Buchan's Well, the position of which had been marked by a wooden pole; but the well itself was completely hidden by a deep snow-drift, which filled the hollow in which it lies. From this spot to the top, the ascent was made almost straight over the snow. At times it was steep and slippery, but the surface was so hard that we rarely sank over the ankles. Two of us were rough shod, one having a few cricketer's spikes screwed to the soles of his boots, the other a pair of *steigeisen* (climbing irons), the use of which he had learned several years ago during some excursions in the Tyrolese Alps. Mr. Maclean, who had not taken these precautions, fell once or twice, but fortunately without being hurt in any way. When near the last slope we descried Mr. Omond hacking away most assiduously with an ice-axe to prepare a way for us, a needless precaution as far as the rough-shod members of the party were concerned.

The view from the plateau on the summit was magnificent. All round there floated a billowy ocean of white mist, from which rose masses of the same, piled up in places like mountain ranges, and through which rose here and there black mountain peaks (prominent among these Schiehallion). Away towards Fort William was stretched a black curtain of mist in striking contrast with the snow-whiteness of the upper layer. Down in Glen Nevis a similar mass was seen, rolled and twisted by the air-currents into the most fantastic shapes. So grand was the spectacle that one of our party insisted that we had before us the model from which Dante had drawn his vision of the entrance to hell.

The summit reached, the directors naturally looked around for the building, whose site they had chosen some five months before, and upon whose construction they had expended so much anxious thought. There was, however, nothing to be seen but two small dark-looking stumps rising a little over the surrounding snow flat, and alongside of these a little mound of snow. The stumps turned out to be the chimney and ventilator on the roof of the observatory, and the mound was a portico built by the observers with blocks of frozen snow to protect a snow staircase which had been carried down the side of the house to the doorway. After descending under the translucent canopy and stumbling for a little in the unfamiliar darkness of the passage, we entered the main room of the observatory, which for the present serves as sitting-room, kitchen, and office combined. Here we found the table laid for our lunch; and very soon we were comforting ourselves with hot coffee, cabin biscuits, and excellent Danish butter from the stores of the establishment. The whole ascent had occupied a little over three hours and a half.

The little room in which we sat contained the American stove which heats the whole observatory, and on which the snow melting and all the cooking is done by John Duncan, the second assistant observer and housemaid. On one of the walls is the combined sideboard and crockery and instrument cupboard; against another stands a small bench with a vice; and on a third is the telegraph instrument, Mr. Omond's desk and book-case, and the drawers in which are kept the records of the observatory. Out of the sitting-room open the three bedrooms for the observers, which resemble very closely the cabins on board a ship; indeed the whole establishment has an intensely nautical air about it, and the visitor steadies himself instinctively now and then, and wonders that the roll never comes.

The rest of the building is occupied with a coal and oil store, and a storeroom in which are kept the cabin biscuits, dried potatoes, tinned soups, meat, and vegetables, lime juice, and medicine chest; which Mr. Omond calculates will support the three observers till June.

The afternoon and evening we spent in watching the observers at work, in dining (which we did very comfortably off the Christmas cheer, viz. roast turkey and plum pudding, provided for the inhabitants of Ben Nevis by a thoughtful friend), and in eager discussion of plans for the present and future work of the Observatory. The routine of the observatory at present consists in hourly observations of the barometer, protected thermometers, dry and wet bulb and maximum and minimum, wind-direction and pressure, rain, snow, sleet or hail, mist, fog or haze, clouds lower and upper, amount, species, and direction, sunshine recorder, miscellaneous, thunder, lightning, haloes, auroræ, meteors, &c., nature and precise time of occurrence of. The self-registering barograph and thermograph now added to the collection of instruments are working very well, and will be invaluable for the record of sudden changes. The protected thermometers and the thermograph are attached to a ladder fixed in the snow. As the level of the snow rises and falls, they are moved from step to step, so as to keep them as nearly as possible to the regulation distance of four feet from the surface. A measurement from the top of the ladder to the surface gives the depth of the snow, which at present varies from six to ten feet at different parts of the summit of the mountain.

Any detailed account of the winter climate of Ben Nevis would be premature and out of place in this notice; but Mr. Buchan has kindly furnished me with an analysis of the meteorological phenomena on Christmas and the following day which were in several respects remarkable.

At 1 A.M. of Christmas day, temperature was 37° 0 from which it steadily fell to 31°·5 at 11 A.M., the air all the time being quite saturated and loaded with dark, gloomy mist, with a barometer steadily rising. The wind was moderate from north-west till 3 A.M., when it changed to west-south-west. About noon the mist pall cleared away and the sun shone out with great splendour. From this hour to midnight, the following most remarkable observations were made (see table).

Except a few cirrus clouds which appeared about one, three, four, and ten o'clock, the sky was cloudless throughout, and during the evening the stars sparkled with unwonted brightness in the dark blue sky.

These remarkable atmospheric conditions were strictly confined to the higher region of Ben Nevis. Fog or cloud covered the lower hills and filled the valleys all the afternoon; it rose sometimes as high as the "plateau of storms," but was mostly below 3000 feet on Ben Nevis, and during the time no other hill showed itself through the sea of cloud. The sunset of the 25th, as well as the sunrise of the 26th, was very beautiful. On the 26th pressure remained high and steady, wind south-westerly, sky generally clear, and temperature and humidity equally remarkable as on the preceding day. Indeed at 2 P.M. the relative humidity, which was lower than could be calculated from Glaisher's Tables, was only 34. At 3 P.M. temperature had fallen 6°·9, humidity risen to 96°, and a light fog prevailed for the next four hours, the wind having shifted from south-west to west-north-west. About 7 P.M. the sky again cleared, temperature steady, rose from 28°·0 to 36°·0 at midnight, and a humidity as low as 67 was observed. The great significance of these observations on Ben Nevis will be more apparent when compared with the anticyclone which overspread so large a part of north-western Europe at the time, to which, being situated on its west side, we owed the mild weather of Christmas, 1883.

In addition to the hourly observations, the observers have had for some time back to conduct a constant warfare with the rapidly-accumulating snow. Every now and then all hands had to be turned out to clear the doors and windows of the observatory; and it sometimes happened that, when they went out for this purpose, the snow drifted in so rapidly that it was almost impossible to shut the door again. The device of the snow staircase got over the difficulty to a large extent as regards the door, and it is proposed to build tubes with short lengths of rectangular wooden framework, passing from the windows up to the surface of the snow. At the upper end of these will be placed, at night or during heavy snowfalls, light canvas doors, which can be afterwards removed and additional lengths of framework added according to necessity. The chimney will be lengthened in a similar way by means of iron tubes, which have been sent up for the purpose. In this way the difficulties of the present winter will be met. For the future it is proposed to get over the difficulty of the accumulating snow by building an observing tower at some little distance from the living-rooms. In this tower there will be several stories with doors to the four cardinal points of the compass, so that the observers may use for exit and entrance that story which is nearest the snow level, and that door which happens to be on the lee-side of the tower. In the ground-floor of this tower it is proposed to place a seismometer and self-registering magnetic instruments. On the roof will be placed an anemometer for measuring the direction and strength of the wind. It is proposed so to arrange this instrument that its indications can be read inside the tower. This appears to be essential, for during the storm on the 12th ult. it was found impossible to go outside the observatory, so that wind observations are wanting in the daily sheet on that very interesting occasion. The observing-tower will be connected with the rest of the buildings by a covered way of some length fitted with doors to cut off the hot air; and in all probability the accommodation of the observatory will be increased by the addition of an office, or experimenting room, and one or more small bedrooms for the use of inspectors or others on temporary business, and for the convenience of scientific men who may wish to make a visit to the observatory for the purposes of scientific research.

For reasons sufficiently explained, the staff has scarcely had time as yet to go beyond the mere routine of observations above mentioned; but none of the valuable suggestions which Mr. Omond and the directors have received have been lost sight of. A beginning has already been made in the collection of meteoric dust; in fact Mr. Murray carried down with him a portion of the residue obtained by melting considerable quantities of surface snow. This is now being examined, and we shall doubtless hear by and by whether it is all of purely local, or partly of volcanic or cosmic origin.

It is intended, as soon as proper arrangements can be made, and the concurrence of the Post Office authorities obtained, to commence a series of simultaneous observations on earth currents along the cable from the summit of Ben Nevis to Fort William, and along a telegraph line from Fort William to some other station not far above sea-level. By means of this horizontal and vertical exploration we hope to obtain some interesting data (either positive or negative) regarding the origin of the variations of terrestrial magnetism, auroræ, &c. The cable will also be turned to account for observations on atmospheric electricity. These plans are mentioned partly to show that the directors are fully alive to the manifold uses to be made of their stronghold upon Ben Nevis, partly to incite scientific men generally to favour us with their suggestions for the full utilisation of the observatory, not only for meteorology, but for physical science in general.

It would take too long to dwell at length on all the interesting casual observations recorded in Mr. Omond's log, a detailed account of which will probably be given hereafter by Mr. Omond himself. It may be interesting, however, to allude to the frequently occurring phenomenon which he calls "Glories." The shadow of the head or hands of the observer is frequently seen on the clouds in the valley to the north-east surrounded by a halo of colour. The phenomenon appears to be akin to, or identical with, the mist phantom so well known under the name of the "Brocken Spectre." The occurrence of this phenomenon is by no means so rare in this country as many suppose. The writer of this notice saw it to perfection three years ago in Skye. A party of four or five of us were standing on Sgur-na-Panachtich, one of the Cuchullin peaks; we were looking down on the dark rock basin of Coruisk, in which was floating a cloud of mist. The sun was low behind us; and, projected on the mist, we saw what appeared to be gigantic dark shadows of ourselves completely outlined with a glory of rainbow colours. Each could see his own spectre best, but also those of his neighbours more or less distinctly. The figures imitated every motion we made, and, when we whirled our alpenstocks over our heads, the antics of the phantoms were most weird and awe-inspiring.

We spent the night of the 26th at the Observatory. During the first watch, that is, up to about one o'clock in the morning, we sat up, and went out with the observer when he made his hourly observations. The air felt quite mild, although the temperature was about the freezing point; the sky was perfectly clear, and the stars shone brilliantly. Mr. Omond brought out his telescope, and we lay down on the snow and examined Jupiter and his satellites, filled our eyes with the beauties of the Pleiades, and exhausted our little stocks of astronomical knowledge by naming such constellations as we happened to know.

The staff had insisted on providing each of us with a bed; we thus had good opportunity of testing their sleeping accommodation, which turned out to be excellent. Next morning we rose to see the sun rise, and were richly rewarded. About eight o'clock a ribbon of bright crimson appeared behind Schiehallion, which deloped a gorgeous succession of tints ending in copper colour and brick red, under the gradually rising sun; to right and left appeared the peculiar green colours so marked in the recent remarkable sunsets, to which the Ben Nevis sunrise showed a great resemblance. The greater part of the horizon was clear, and we had a view of the surrounding mountains seldom, if ever, equalled in summer time for beauty of colour. Ben More, the range of Glencoe, the Perthshire Hills, the whole length of the Caledonian Canal, the Cuchullin Hills, could all be seen with perfect distinctness. The white snow on the black-blue hilltops, and the bright red of the withered heather and bracken lower down, afforded contrasts of colour to be seen at no other season. Some of the hillsides shone in the sunlight like bronze. Others glowed like the richest velvet, and the valleys were filled with the subtle blue haze that gives such a charm to the scenery of the west of Scotland.

We naturally congratulated Mr. Omond on the weather he enjoyed on Ben Nevis; but it appeared that the treat was as great for him as for us. Since he began his seclusion on November 11, there had been just three fine days —the day on which he went up, Christmas day, and the day following, all the rest of the time the most he had seen was an occasional glimpse of a snow-covered mountain-peak through a hole in the mist. Our good fortune had been great; and, although it might have suited the main purpose of our visit better to have been detained by mist and sleet, or to have seen the observatory in the process of being buried in a snow-drift, we resigned ourselves with a very good grace to what the Fates had sent us.

After sharing the regulation breakfast of tinned mutton and coffee, we went out once more to see the observers at work. We then had an opportunity of seeing the precautions which they find it necessary to take in tempestuous weather when they have occasion to go near the edge of the narrow plateau on which they live. For sanitary reasons it is necessary to carry all the refuse of the observatory to a considerable distance, where it is thrown over a cliff. In winter, when this cliff is covered with a treacherous cornice of slippery snow, and the wind blows so hard that the head of a meat tin thrown to windward is often carried right back to leeward of the mountain, the footing at the edge is anything but secure. On such occasions two of the observers go abreast with the pail of rubbish between them, and each is roped to one who goes behind with an ice-axe to steady him in case of accident.

By 11 o'clock the barometer had begun to fall, and the humidity of the air had greatly increased. Mr. Omond therefore warned us that, unless we were prepared to incur the risk of detention, we had better depart. Accordingly we packed up our trophies, consisting of the residue above mentioned, pregnant with the potentiality of cosmic and volcanic dust, a bundle of Mr. Omond's daily sheets, and a little shrew that had been killed on the previous evening, the first of a colony of these animals who, with several weasels, had taken up their abode in the outer dry stone wall of the observatory. As might be expected, animal life is very scarce in winter on the top of Ben Nevis. No deer or ptarmigan had been seen, only the tracks of foxes, which abound in certain parts of the hill. The only living things we had seen in the snow-covered part of the hill were large numbers of a dipterous fly, which we found every now and then crawling on the surface of the snow.

Having bidden farewell to Mr. Omond and his companions, and wished them good luck and a continuance of their present good health and spirits during the rest of the winter, we commenced our descent at 11.30. The bottom was reached, after several halts to enjoy the magnificent view, in about the same time as it had taken us to ascend.

In such weather as we had the ascent of Ben Nevis is decidedly more pleasant and less fatiguing than in summer. It is well, however, to warn the readers of NATURE that our case was exceptional, and that under adverse circumstances such an enterprise is likely to be both unpleasant and dangerous. G. CHRYSTAL

THE REMARKABLE SUNSETS

INFORMATION with regard to these beautiful phenomena and their cause is rapidly being collected, and at the same time the opinions of those who have given most attention to them are being stated, both here and on the Continent. Among the latter we may refer to a memoir presented by Prof. Forel to the Société Vaudoise des Sciences Naturelles, on the 19th of December. At the beginning of the displays in Switzerland, M. Forel ascribed them to those causes which produce the ordinary after-glow so beautifully visible in mountainous countries, and at first he considered that the meteorological conditions were such as to favour this view. Further inquiry, however, he now states has made this hypothesis absolutely untenable. One of his arguments is that the glows which first appeared in November and then decreased to 3rd December, regained a maximum on the 24th and 25th. Now from the 22nd to 26th December, Switzerland was the centre of a maximum of atmospheric pressure, the barometer being higher there than in any of the surrounding countries. Exactly the opposite held in November, and this confirms him in the idea that meteorological factors alone do not suffice to explain the glows. He also describes the dates and tracts of the chromatic phenomena observed, and considers that their origination in Krakatoa is a simple and sufficient explanation. *La Nature* for the 29th ult. contains an interesting communication from M. Van Sandick, an Engineer des Ponts et Chaussées, at Pedang, who was an eye witness of the later stage of the eruption. He was on board the *Governor-General Loudin*, and was close to Krakatoa on August 26th. His communication is accompanied by a very detailed map, showing the changes which have supervened not only in the Straits themselves, but also on the neighbouring coasts of Java and Sumatra, but we shall return to this important letter.

The new observatory on the summit of Ben Nevis has been utilised for the collection of snow, with a view of determining whether or not it contains any dust particles. This has been forwarded to Mr. John Murray of the *Challenger* Commission by Mr. Omond the superintendent of the observatory. We may hope to hear soon whether the results are positive or negative on this special point of inquiry. We have to call attention to the important letter of Mr. Macpherson published below. We learn from the *Weekly British Colonist*, published at Victoria, British Columbia, that the sunsets made their appearance there on November 27th. Long after sunset the light in the sky became more fervent in colour, till at last the waters in the harbour and straits borrowed the splendid crimson. Darting and rapidly moving blood-red rays of light were seen shooting far into the sky, suggesting an aurora. A letter from St. Raphael, on the shores of the bay of San Francisco, dated December 4th, refers to the magnificent sunrises and sunsets. The date of their commencement is not stated. From Kiakhta, on the Mongolian frontier, we learn that the glows there began on December 11th, and terminated on the 25th.

The glows were seen some time before November 6th at Kalim Pong, twenty miles north-west of Darjeeling.

We have received the following further communications on this subject:—

THE body of evidence now brought in from all parts of the world must, I think, by this time have convinced Mr. Piazzi Smyth that the late sunrises and sunsets do need some explanation, more particular than he was willing to give them. With your leave I should like to point out from my own observations and those of others that, "given a clear sky" and the other conditions put by Mr. Smyth, the sunrises and sunsets of other days, however bright and beautiful, have *not* given any such effects as were witnessed, to take an instance, here on Sunday night, December 16th. I shall speak chiefly of the sunsets.

(1.) *These sunsets differ from others, first in their time and their place or quarter.* Sunset proper is, I suppose, the few minutes between the first dipping and the last disappearance of the sun's disk below the true horizen; the pageant or phenomena we call sunset, however, includes a great deal that goes on before and after this. The remarkable and specific features of the late sunsets have not been before or at sunset proper; they have been after-glows, and have lasted long, very long, after. To take instances from your number of the 13th ult., Mr. F. A. R. Russell notices that on November 28th, the sun having set at 3.55, one after-glow lasted till 5.10, and was then succeeded by another "reaching high above the horizon." The day before he mentions the after-glow as lasting to 5.20. On the 29th a "foreglow" is reported as seen in London from 5.30 to 7.30, that is more than two hours before sunrise, which was at 7.43. On December 1st, sunset being at 3.53, Mr. Russell observed an after-glow till 5.35; on December 4th the first dawn at 6.5, the sun rising at 7.50; the next day dawn at the same time, sunrise 7.51; that evening, sunset being at 3.50, he observed not a glow only but "spokes of rays from the glowing bank" at 4.45, thatis to say, sunbeams, visible in the shape of sunbeams, 55 minutes after sunset. Mr. Johnston-Lavis speaks of the after-glow at Naples as *at a maximum* an hour after sunset. Here at Stonyhurst on December 16th, the sun having set at 3.49, the glow was observed till 5.50. Now winter dawns and after-glows do not last from an hour to two hours, and still less so day after day, as these have done. The recent sunrises and sunsets then differ from others in duration.

They differ also in the quarter of the heavens where they are seen. The after-glows are not low lingering slips of light skirting the horizon, but high up in the sky, sometimes in the zenith.

I have further remarked that the deepest of the after-glow is in the south, whereas the sun below the horizon is then northing. I see that other observers take notice of the same.

(2) *They differ in their periodic action or behaviour.* The flushes of crimson and other colours after ordinary sunsets are irregular, not the same nor at the same time for two days together; for they depend upon the accidental shapes and sizes and densities of the cloud-banks or vapour-banks the sun is entering or freeing himself from, which vary and can never be alike from day to day. But these glows or flushes are noticed to be periodic before sunrise and after sunset. Mr. Russell furnishes exact estimates of the intervals of time, which he finds to be the same day after day.

(3) *They differ in the nature of the glow, which is both intense and lustreless,* and that both in the sky and on the earth. The glow is intense, this is what strikes every one; it has prolonged the daylight, and optically changed the season; it bathes the whole sky, it is mistaken for the reflection of a great fire; at the sundown itself and southwards from that on December 4, I took a note of it as more like inflamed flesh than the lucid reds of ordinary sunsets. On the same evening the fields facing west glowed as if overlaid with yellow wax.

But it is also lustreless. A bright sunset lines the clouds so that their brims look like gold, brass, bronze, or steel. It fetches out those dazzling flecks and spangles which people call fish-scales. It gives to a mackerel or dappled cloudrack the appearance of quilted crimson silk, or a ploughed field glazed with crimson ice. These effects may have been seen in the late sunsets, but they are not the specific after-glow; that is, without gloss or lustre.

The two things together, that is intensity of light and want of lustre, give to objects on the earth the peculiar illumination which may be seen in studios and other well-like rooms, and which itself affects the practice of painters and may be seen in their works, notably Rembrandt's, disguising or feebly showing the outlines and distinctions of things, but fetching out white surfaces and coloured stuffs with a rich and inward and seemingly self-luminous glow.

(4) *They differ in the regularity of their colouring.* Four colours in particular have been noticeable in these after-glows, and in a fixed order of time and place—orange, lowest and nearest the sundown; above this, and broader, green; above this, broader still, a variable red, ending in being crimson; above this a faint lilac. The lilac disappears; the green deepens, spreads, and encroaches on the orange; and the red deepens, spreads, and encroaches on the green, till at last one red, varying downwards from crimson to scarlet or orange fills the west and south. The four colours I have named are mentioned in Lieut. G. N. Bittleston's letter from Umballa: "The sun goes down as usual and it gets nearly dark, and then a bright red and yellow and green and purple blaze comes in the sky and makes it lighter again." I suppose the yellow here spoken of to be an orange yellow, and the purple to be what I have above called lilac.

Ordinary sunsets have not this order; this, so to say, fixed and limited palette. The green in particular, is low down when it appears. There is often a trace of olive between the sundown and the higher blue sky, but it never develops, that I remember, into a fresh green.

(5) *They differ in the colours themselves, which are impure and not of the spectrum.* The first orange and the last crimson flush are perhaps pure, or nearly so, but the two most remarkable glows, the green and the red, are not. The green is between an apple-green or pea-green (which are pure greens) and an olive (which is a tertiary colour): it is vivid and beautiful, but not pure. The red is very impure, and not evenly laid on. On the 4th it appeared brown, like a strong light behind tortoiseshell, or Derbyshire alabaster. It has been well compared to the colour of incandescent iron. Sometimes it appears like a mixture of chalk with sand and muddy earths. The pigments for it would be ochre and Indian red.

Now the yellows, oranges, crimsons, purples, and greens of bright sunsets are beautifully pure. Tertiary colours may of course also be found in certain cases and places.

(6) *They differ in the texture of the coloured surfaces,* which are neither distinct cloud of recognised make nor yet translucent mediums. Mr. Russell's observations should here be read. I have further noticed streamers, fine ribbing or mackerelling, and other more curious textures, the colour varying with the texture.

In ordinary sunsets the yellows and greens and the lower reds look like glass, or coloured liquids, as pure as the blue. Other colours, or these in other parts, are distinct flushes or illuminations of cloud or landscape.

I subjoin an account of the sunset of the 16th, which was here very remarkable, from my own observations and those of one of the observatory staff.

A bright glow had been round the sun all day and became more remarkable towards sunset. It then had a silvery or steely look, with soft radiating streamers and little colour; its shape was mainly elliptical, the slightly longer axis being vertical; the size about 20° from the sun each way. There was a pale gold colour, brightening and fading by turns for ten minutes as the sun went down. After the sunset the horizon was, by 4.10, lined a long way by a glowing tawny light, not very pure in colour and distinctly textured in hummocks, bodies like a shoal of dolphins, or in what are called gadroons, or as the Japanese conventionally represent waves. The glowing vapour above this was as yet colourless; then this took a beautiful olive or celadon green, not so vivid as the previous day's, and delicately fluted; the green belt was broader than the orange, and pressed down on and contracted it. Above the green in turn appeared a red glow, broader and burlier in make; it was softly brindled, and in the ribs or bars the colour was rosier, in the channels where the blue of the sky shone through it was a mallow colour. Above this was a vague lilac. The red was first noticed 45° above the horizon, and spokes or beams could be seen in it, compared by one beholder to a man's open hand. By 4.45 the red had driven out the green, and, fusing with the remains of the orange, reached the horizon. By that time the east, which had a rose tinge, became of a duller red, compared to sand: according to my observation, the ground of the sky in the east was green or else tawny, and the crimson only in the clouds. A great sheet of heavy dark cloud, with a reefed or puckered make, drew off the west in the course of the pageant: the edge of this and the smaller pellets of cloud that filed across the bright field of the sundown caught a livid green. At 5 the red in the west was fainter, at 5.20 it became notably rosier and livelier; but it was never of a pure rose. A faint dusky blush was left as late as 5.30, or later. While these changes were going on in the sky, the landscape of Ribblesdale glowed with a frowning brown.

The two following observations seem to have to do with the same phenomena and their causes. For some weeks past on fine bright days, when the sun has been behind a big cloud and has sent up (perspectively speaking) the dark crown or paling of beams of shadow in such cases commonly to be seen, I have remarked, upon the ground of the sky, sometimes an amber, sometimes a soft rose colour, instead of the usual darkening of the blue. Also on moonlight nights, and particularly on December 14, a sort of brown or muddy cast, never before witnessed, has been seen by more than one observer, in the sky. GERARD HOPKINS

Stonyhurst College, December 21, 1883

THE remarkable phenomena after sunset which, according to NATURE, were seen in the second half of November in England, Italy, at the Cape, and a little earlier in many parts of Asia, could be observed almost all over Austria and Germany. I saw them myself in an especially distinct appearance here on November 22 and 29. Soon after sunset on November 22 (at 4.30 p.m.), a crimson glow was seen in the direction of south-west, and while everybody was supposing that some large printworks lying in that direction were on fire, the glow was getting more intense, and at 5 p.m. the whole of the western sky assumed a bluish purple hue which rose up to the zenith while the sun was sinking lower, so that the glow could be attributed only to an atmospheric phenomenon. About an hour after sunset the colour of the sky was almost violet, with which the phenomenon disappeared.

According to German papers, a phenomenon of this kind and intensity was never before observed in Central Europe. Dr. Assmann, director of the Meteorological Observatory, Madgeburg, attempts to explain these phenomena by the reflection of sunlight from the upper strata of our atmosphere, highly saturated with aqueous vapour, owing to its comparatively high temperature. The phenomenon could not be attributed to electrical causes, as at that time not the slightest magnetic disturbance could be observed at the Prague Observatory. In the spectrum of this light uncommonly strong "rain bands" were seen. As the sun was about 18¾° below the horizon when the phenomena began (before sunrise) or ceased (after sunset), the reflection was calculated to have taken place at a height of about fifty English miles.

Does it not strike you that the glow was observed at earlier periods the more we advance towards the east—the source of the late Java eruptions? B. Brauner

Bohemian University, Prague, December 18, 1883

The late splendid sunsets which have so vividly attracted the attention of men of science and of the general public were so remarkable and of so long a duration in the clear atmosphere of the Castilian tableland, where sunsets are usually dull, that they have not failed to impress observers with the notion that they were due to other causes than those of common atmospheric refraction and reflection.

When the phenomena had already lasted four or five days, I read Mr. Symons' letter, published in the *Times* of the 1st inst., and I thought that possibly evidence might be obtained towards the confirmation of this theory if the sediment of fresh-fallen snow was thoroughly investigated; for if the dust of Krakatoa was really reflecting in the higher regions of the atmosphere the sun's rays, some of it must necessarily be descending towards the earth.

Luckily on the 7th of this month, and when the phenomenon was at its height, and had already lasted for about eight days, there was a fall of snow at Madrid, of which I naturally profited, submitting it to a thorough investigation, the results of which, I think, will throw some light on so remarkable a phenomenon.

The snow analysed was obtained from what had fallen on some zinc plates before the exposed windows to the north of my house, which is situated at the extreme north end of the town, where there are no buildings facing it, and also from what my friend Dr. Francisco Quisoga gathered from the windows of his house, situated about a mile to the south-east of mine; and in both the same substances were found.

The snow yielded about a litre of water, which, when the sediment had collected, was decanted, and the solid part dried at a temperature below that of boiling water. The dry powder was then tested for magnetism and it was found to be extremely magnetic. It was then incinerated on platinum foil to a bright red heat so as to destroy organic substances, and the remaining dust was then submitted to microscopical investigation. The greater part of it is made up of what probably is the natural dust of the atmosphere of Madrid; of particles of mica, generally brown, and similar to that of the Guadarrama range, and in various states of decomposition, splinters of quartz and felspar, the greater part of it orthoclase, some small fragments of tourmaline, magnetic iron, and fragments of diatoms. Besides these mineral substances, which may probably be traced to the rocks forming the vicinity of the capital, some others were found for the presence of which it is difficult to account. The most remarkable are small particles of a foliated mineral of a yellowish colour, perceptibly dichroic, and which between crossed Nichols is extinguished when the cleavage traces are parallel to the principal section of the polarising Nichol; the interference colours being of bright blue, and red, and yellow colours. Treated by boiling hydrochloric acid for twenty minutes, not a trace of action was perceived. These characters are all referable to a rhombic pyroxene, and judging from its dichroism this substance may be taken for a hypersthene, which has besides a most striking resemblance to volcanic hypersthene. In addition to this mineral, small particles are found which appear to be referable to common pyroxene of a yellowish colour, of active action in polarised light, and the extinction not taking place parallel to what seem to be the edges of the prism. Besides these minerals some corpuscles are found of hardly any action on polarised light, and sometimes full of globular concretions and other kinds of microliths, which, if seen in products of a volcanic region, I would not hesitate in considering of volcanic origin.

These are the principal substances which an investigation of the sediment of the snow which fell in Madrid on the 7th inst. have revealed, and though I am far from asserting that what appears to be foreign to the atmosphere of this part of the world is referable to the dust of Krakatoa, if further analyses in other parts of the world should show these same substances floating in the atmosphere, there would be powerful reasons for inferring that the gorgeous sunsets of the past months have been brought about in consequence of that stupendous display of the volcanic forces of our globe.

It is already a remarkable coincidence that hypersthene should have been found both by MM. Daubrée and Renard in their respective analyses of the ashes collected in the vicinity of Krakatoa. Joseph Macpherson

Madrid, December 22, 1883

Complying with the request contained in your "Notes" of December 13 (p. 157), I would say that the appearances, already fully described by so many of your correspondents, commenced here on December 1. On that day I made an entry in my note-book as follows:—"Perfectly calm at sunset, with a light haze of a rose tint rolling away from overhead towards the west-south-west horizon. The colours of the sky were a very pale green, red, gold, and pink; and, as the light faded away, the south-west was one mass of deep rich red. The crescent moon (a little over eighteen days old) in the refractor was of a pale green colour, and the bright limb seemed to extend to an extraordinary distance round the dark body. Barometer falling."

Again: "December 2.—Sky clouded over by 1 p.m. Sunset, as seen between breaks in the clouds, was again of a deep rich red. Barometer steady."

"December 3.—Rainy and very dull. Barometer steady."

"December 4.—Sunset, as seen through the clouds along the horizon, was again of a deep red colour, gradually shading off into a pale rose tint towards the zenith. The moon, Fomalhaut, and Vega seemed to float in a pale rose sea; whilst thin fleecy clouds as they drifted across the moon's face were of a beautiful pale green. This appearance—as did that on the 1st—lasted for about an hour and a quarter after sunset; the rest of the sky being covered with clouds, some faintly reflecting the various tints. Barometer falling."

I should not omit to mention that the sunrises were also, more or less, of similar character. Since the 4th we have had very bad weather; gales from both north and south, heavy rains, and snow. Yet the sky, when occasionally glimpsed at sunset, seems to bear traces of the same appearances. W. E. J.

Constantinople, December 21, 1883

In addition to the remarkable sunsets which have led to such a large amount of correspondence in Nature and elsewhere, there is another and possibly a related phenomenon to which my attention has been directed during the last few weeks. From country friends I learn that the nights, in the absence of the moon, and even when cloudy, have been remarkably light for the time of year. I cannot profess to have witnessed this phenomenon myself, living as I do in the midst of London, where the perpetual glare of gas renders any satisfactory estimate of the atmospheric luminosity quite hopeless. It would be interesting, however, to learn whether other observers more favourably located have noticed this effect. It occurred to me that the phenomenon might perhaps be connected with the volcanic dust theory of the sunsets, being, in fact, a result of the slight phosphorescence of this dust. Whether the latter exhibits any degree of phosphorescence could be readily determined by those who are fortunate enough to possess a specimen, by means of Becquerel's phosphoroscope.

R. MELDOLA

21, John Street, Bedford Row, W.C., Dec. 31, 1883

IN corroboration of what Messrs. Beyerinck and Van Dam noticed at Wageningen in connection with the late storm, I write to tell you that on the morning of December 12, after the heavy rain which accompanied the gale had ceased, the windows of my house, which is isolated and exposed, were covered with a grayish sediment, just as your correspondents describe it. It will be interesting, now that attention has been drawn to the fact, to know if the phenomenon, the result no doubt of dust brought down by the rain, has been observed elsewhere.

F. M. BURTON

Highfield, Gainsborough, December 24, 1883

I SUBMIT to you two slides of dust from windows, deposited during the storm of December 12. When the contained salt crystals are dissolved by adding distilled water, the appearance much resembles that recorded in NATURE of December 20. The material, scraped from windows cleaned just before the storm, where the original drop-marks are still unaltered, was put on the cleaned slides, and a drop of distilled water added. Should my surmise be confirmed, and any of your readers desire to have specimen slides, I would forward a limited number on receipt of sixpence each to cover postage and trouble. Descriptions I have received from America, either in letters or newspaper cuttings, show an identical sequence of appearances. At Poughkeepsie, on the Hudson, the fire-engines were called out on the morning of November 27, and "this spectacle has been witnessed every clear evening for several days past, generally between a quarter past five and six o'clock." A letter from Dorset, Vermont, November 29, describes "a very unusual exhibition in the skies for the past three or four evenings. It has been clear, and the colouring intense, from flame to a delicate pink, and the clouds off at a distance would look light green. . . . It gave an impression of an intense fire the other side of the West Mountains, and colouring the entire sky."

J. EDMUND CLARK

York, December 22, 1883

THE accompanying extract may be of service to you. Sapporo is in the northernmost island of Japan (Yeso), in lat. 43° N., and long. (*circa*) 141° E. As the telegraph ramifies through all parts of Japan, it is improbable that any considerable local eruption would have taken place to account for the phenomenon without news of it having also reached the *Official Gazette*.

ROBERT BEADON

11, Lee Park, Lee, Kent, December 14, 1883

Extract from *Japan Weekly Mail* (published in Yokohama) of October 20, 1883. (The *Official Gazette* is the Government gazette published in Japanese.)—" The *Official Gazette* states that, since the 13th inst., a constant haze has pervaded the atmosphere of Sapporo, and that the sun and moon are of a blood-red colour. Clouds of ashes fall continuously. The phenomenon is ascribed to some volcanic eruption."

NOTES

PROF. OWEN has received the honour of K.C.B. as an acknowledgment of his eminent services for sixty years to science and the public interests.

PROF. W. H. MACKINTOSH has been elected to the Professorship of Comparative Anatomy in Trinity College, Dublin, vice Prof. Macalister, F.R.S., who resigned on his appointment to the Anatomy Chair at Cambridge.

BY the death of the well-known mathematician, the Rev. W. Roberts, M.A., the Rev. Richard Townsend, M.A., F.R.S., becomes a Senior Fellow of Trinity College, Dublin, thereby vacating the Professorship of Natural Philosophy held by him since 1870.

THE vacancy in the Professorship of Geology and Mineralogy in the University of Dublin has been filled by the election of Prof. Sollas, of University College, Bristol. This appointment will give great satisfaction, and will afford Mr. Sollas large opportunities for palæontological research; the large collections of fossil plants and vertebrates in the museum in Dublin remaining to this day almost unknown.

THE Swedish Government intend to establish a botanico-physiological station in the north of Sweden for the study of the flora and the diseases of the crops in that part of the country.

THE Finnish Government have ordered a steamer to be specially built in Sweden for the scientific researches about to be prosecuted in the Baltic.

M. HOUZEAU, who was only recently appointed director of the Brussels Observatory, has resigned his post, and it is reported that M. de Konkolly of Gzalla Observatory, Hungary, will succeed him.

PROF. MAURICE LEVY has been nominated member of the Paris Academy of Sciences in the Section of Mechanics.

THE Prince of Wales, as President of the Society of Arts, has transmitted to Lady Siemens the resolution passed after the death of Sir William Siemens, by the Council of that Society, and in doing so has expressed his own appreciation of Sir William Siemens's labours.

SCIENCE had quite a field-day in Perth on December 20, when the Natural History Society of the Fair City formally opened its museum. Prof. J. Geikie of Edinburgh, who was for some time president of the Society, opened the proceeding with an address in which he pointed out what such a local museum should be. Other speakers followed, and from the 20th to the 23rd was an almost continuous *conversazione*, in which exhibitions, demonstrations, and lectures were given. The electric light played a prominent part, and the objects brought together for the instruction and enjoyment of the many visitors represented all departments of science. The enterprise of the Perthshire Society is exceptional, and they have reason to be proud of their museum, reading, lecture, and other rooms, all of which, we have no doubt, will be put to excellent practical uses.

THE meteorological observations taken during October, 1883, at St. Ignatius' College, Malta, by the Rev. James Scoles, S.J., have been received. For the month the means were—pressure, 30·283 inches; temperature, 67°·98; daily range, 10°·2; elastic force of vapour, 0·498 inch, and humidity, 76; rainfall, 2·67 inches, and days of rain, 12; velocity of wind per hour, 8½ miles; sky, a third covered with cloud; temperature of sea, 72°·0, with a monthly range of 4°·0; and thunderstorms and other electrical phenomena on the 4th, 10th, 11th, 12th, 13th, 15th, 26th, and 30th. Atmospheric pressure was thus fully a fourth of an inch below the mean, temperature 3°·4 lower than usual, and rainfall about half an inch less. This Society has peculiar facilities for prosecuting meteorological and other researches through its widely scattered seminaries and colleges, and we have the greatest pleasure in noting the increasing readiness with which its services are given to science.

MR. H. H. JOHNSTON will give a discourse on "Kilimanjaro, the snow-clad Mountain of Equatorial Africa," at the Royal Institution, on Friday evening, January 25. Prof. Bonney's discourse on "The Building of the Alps," announced for that evening will be given on April 4.

HERR STEINEGER has been so fortunate as to secure eleven crania and numerous bones of the extinct sea-cow, *Rhytina stelleri*, which have been forwarded to the Smithsonian Institution at Washington.

A SPLENDID meteor was seen at Frankfort-on-the-Maine on December 8 at 6.45 a.m. It moved from west to east, and illuminated the whole neighbourhood.

A *Times* correspondent writes from Iceland that reports of a volcanic eruption in the interior were current last year, and were founded on peculiar appearances of the sky, and especially on the observation from some of the remote inland farms of columns of smoke or vapour rising in the far distance. Nothing definite has, however, been ascertained as to these phenomena. An unusually large number of scientific men, geologists, botanists, and philologists, chiefly German and Swedish, have this year visited Iceland and investigated its structure, flora, and language; and at present Prof. Sophus Tromholt, well known in scientific circles by his researches as to the aurora borealis, is pursuing these investigations here, and intends to remain all the winter, as, from the clearness of the atmosphere and the frequency and brilliancy of the aurora, Iceland is exceedingly well suited for his observations.

THE extensive collections of American Coleoptera made by the late Dr. J. L. LeConte, containing an immense number of original types, become the property of the Museum of Comparative Zoology of Cambridge, Mass.

THE French Société des Électriciens has completed its arrangements, and has been divided into six sections:—Theoretical electricity, M. Marie Davy president; Dynamo-electrical machinery, transmission of force to a distance, distribution of energy, M. Tresca president; Electric lighting, M. Du Moncel president; Telegraphy and telephony, M. Blavier president; Electro-chemistry and electrotherapy, M. Jamin president.

WHEN Arago was director of the Observatory of Paris, the dotation of this establishment was less than 4000*l*. a year. This sum was greatly increased when Leverrier was appointed by Napoleon III., and before his death it had reached 10,000*l*. Now the sum allotted is about 16,000*l*., although the meteorological department has been set apart as a special service.

THE Italian Geographical Society awards its great gold medal to Count Pietro Antonelli, in consideration of the important results of his last journey to Shoa.

FROM advanced sheets of the *Proceedings of the Anthropological Society of Washington*, Col. F. A. Seely of the United States Patent Office, we learn from *Science*, publishes a pamphlet entitled "An Inquiry into the Origin of Invention." The author is accustomed, day by day, as new claims for patents come before him, to eliminate the successive steps in the classes of machinery until he reaches the fundamental idea. This is the plan pursued in tracing backward the whole subject of invention to its sources in the mind of primitive man. The subject is illustrated, first, by the story of the steam-engine, and then by the examination of the bow and arrow and other implements of the lower races. The author rejects Prof. Gaudry's Dryopithecus, and affirms, "Obviously, archæology can find no trace of a remoter age than that of stone; but I mistrust that the thoughtful anthropologist will accept the evidence of earlier ages, one of which, taking one of its perishable materials as the type of all, we may call the age of wood. Still farther back must lie an age, as indefinite in duration as any, when man existed in his rudest condition, without arts of any kind, except such as he employed in common with lower animals; and this is the true primitive period."

WE have received the report for the years 1880 and 1881 of the administration of the artistic and scientific collections in the Royal Museums of Dresden. The Zoological and Anthropological Museum was visited by 61,129 persons in 1880, and by 65,455 in 1881. An index to Reichenbach's ornithological works has been prepared by the director, Dr. A. B. Meyer, who has also issued an important work on the picture-writings of the Eastern Archipelago and Pacific Islands. The staff of this museum now consists of the Director, Th. Kirsch, curator, L. Römer and J. C. G. Wilhelm, first and second conservators, C. A. Kippe, preparer of specimens, a scientific assistant, and two attendants. The zoological and anthropological collections were enriched in the years 1880 and 1881 by 2242 specimens of the higher animals, and 17,753 of insects, by 237 anthropological and 1351 ethnographic objects, including 61 crania and 56 photographs and drawings of human types from various quarters. The library attached to this department was increased by 332 works, including donations from the British Museum, Smithsonian, and other sources. The systematic catalogue of the fishes was completed in three volumes, with alphabetical index of the 294 genera, 726 species, and 2901 specimens contained in the collection. The nests, to the number of 800, were also rearranged and catalogued, and progress was made with the catalogues of the birds (from No. 1688 to 2948) and insects (Hymenoptera concluded, Diptera thoroughly revised, of Coleoptera three families arranged and catalogued).

MESSRS. BAILLIÈRE AND CO. of Paris have issued the first number of a new scientific weekly, *Science et Nature*, profusely illustrated.

M. ÉD. MAILLY has brought out, in two volumes, a "Histoire de l'Académie Impérial et Royal de Bruxelles," from which so much good work has emanated. The history abounds in interest. F. Hayez of Brussels is the publisher.

SPAIN does seem to be progressing in the right direction. We have the second volume of Mr. F. Gillman's very useful and carefully compiled "Enciclopedia-Popular Illustrada" (Madrid), with a large atlas of plates. Also the first number of *La Industria Ibérica*, a weekly paper devoted to the industry and science of the whole peninsula, well printed, and, to judge from the first number, judiciously edited.

MESSRS. CHARLES GRIFFIN AND CO. announce the following scientific publications as forthcoming:—"A Manual of Geology," by Robert Etheridge, F.R.S., and Prof. H. G. Seeley, F.R.S.; "A Manual of Chemistry," by Prof. Dupré, F.R.S., and Dr. H. Wilson Hake; "A Manual of Botany: the Morphology, Physiology, and Classification of Plants, for the Use of Students," by Prof. W. R. M'Nab; "A Pocket-book of Electrical Rules and Tables, for the Use of Electricians and Engineers," by John Munro, C.E., and Andrew Jamieson, C.E., F.R.S.E.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Miss P. Crabtree; a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, presented by Mr. Walter van Weede; an Alligator (*Alligator mississippiensis*) from the Mississippi, presented by Mr. Thick; a Ring-tailed Coati (*Nasua rufa*) from South America, deposited.

PHYSICAL NOTES

M. E. REYNIER has described, in *l'Électricien*, a research made by him on the maxima and minima of electromotive force of certain batteries in which polarisation takes place. These he calls "single-electrolyte" batteries, instead of "single-fluid" batteries, following a suggestion of the late M. Niaudet. The difference consists in the relative size of the electrodes. For example, in the case of a zinc-copper cell containing a single electrolytic fluid, the maximum cell is made with a kathode of sheet-copper folded and curved, presenting 300 times as much surface as the thin copper rod which serves as anode, whilst in the minimum cell the proportion is reversed, so that the polarisation at the surface of the copper attains at once its maximum value. The value of the E.M.F. of the cells when filled with dilute sulphuric acid, and having the zinc amalgamated, was 1·072 volts maximum, and 0·272 volts minimum. Many other electrolytes were examined by M. Reynier. The electromotive force was measured upon a galvanometer of high resistance.

M. REYNIER has suggested a modification of his maximum cell to serve as a standard of electromotive force—namely, a cell having a very large copper electrode, and a very small amalgamated zinc electrode, immersed in a solution of sea-salt. According to M. Reynier, this battery has an E.M.F. of 0·82 volts, and maintains this value within 1 per cent. even when the circuit was loosed for two hours through a resistance of 820 ohms. M. Reynier prefers this combination to one containing sulphate of zinc in solution, because of the liability of the latter salt to contain free acid.

M. HENRI BECQUEREL has been pursuing his researches upon the infra-red rays of the spectrum. For the investigation of this region there are four methods, the first of them involving the use of a line-thermopile and a rock-salt prism; the second, Abney's photographic method; the third, Langley's method, with bolometer and a reflecting diffraction grating; the fourth, that of Becquerel, depending upon the discovery that the infra-red rays have the effect of extinguishing the glow of a phosphorescent body exposed previously to ultra-violet rays. M. Becquerel finds that water, for example, gives in the region to which this method is applicable three well marked absorption-bands, having wave-lengths respectively of 930, 1080, and 1230.

THE newest result of Becquerel's researches is worth more than passing mention. He finds that there exist in this wholly invisible region of the spectrum bright-line spectra—equally invisible, of course—just as in the visible parts of the spectrum, observable in the radiations of hot vapours. Thus, incandescent sodium vapour prints upon the previously "insolated" phosphorescent substance two well-marked lines (wave-lengths 819 and 1098), corresponding to two bright lines hitherto unknown. The extent of the region which is capable of being explored by this novel process is from wave-length 760 to 1300, or exceeding in extent that of the whole of the visible and ultra-violet rays.

AN interesting experiment is described in the *Zeitschrift des elektrotechnischen Vereins*, in Vienna, by Prof. von Waltenhofen, made by means of Noe's thermo-electric generators. If a current from a voltaic battery has been sent for a few moments through one of these generators, it is capable of yielding a discharge like a secondary battery. This effect is so far a mere repetition of a well-known experiment of Peltier, and is due to the change of temperature at the junction, called the Peltier effect. But von Waltenhofen observes that the effects are different according to the sense of the charging current. In one case, with increasing charging currents the discharge currents also increased, and were always in the opposite sense to that of the charging current. But when the charging current was reversed, it was found that with increasing charging currents the discharge currents at first increase, then attain a maximum, then decrease to zero, then actually recommence in the converse sense, namely, in the same sense as that of the charging current. Prof. von Waltenhofen is disposed to attribute this anamalous result to the lack of symmetry in the disposition of the alternate solderings of the generators, and to their alternately unequal resistance causing alternately unequal developments of heat due to resistance.

IN proof of the law of proportion between the thickness of a square vibrating plate and its pitch, Dr. Elsas gives the following neat experiment. Let three plates be cut from the same sheet of material, of the same size and form. Cement two of these together so as to produce a plate of double thickness Then, on exciting the single plate and the double plate by communicating to them respectively the vibrations of two tuning forks whose pitches are as 1 : 2, the plates will be excited in identical manners, as will be seen by dusting sand upon them, the clang-figures being identical.

LORD RAYLEIGH has reprinted for private circulation in pamphlet form several of his most valuable optical papers, including those on the manufacture, reproduction by photography, and theory, of diffraction-gratings, and those on colour-mixtures.

LORD RAYLEIGH has also reprinted some of his papers on electricity and on absolute pitch, from NATURE and from the Reports of the British Association, in a convenient pamphlet form.

THE question whether condensation of steam is a cause of electrification has been examined afresh by S. Kalischer in the Physical Laboratory at Berlin. According to the views of Faraday, this is a cause of electrification, and upon the alleged phenomenon Prof. Spring has founded a theory of the origin of thunderstorms. Landerer thought he had heard sounds in the telephone due to condensation of moisture on the line wires. Kalischer has in vain repeated the experiment. He has also examined, by means of the quadrant electrometer, whether any such electrification could be observed from the deposit of moisture upon the surface of a vessel containing ice or some artificial cooling mixture. The whole of the results were negative.

AMONGST the many recent suggestions for primary batteries is one due to MM. Lalande and Chaperon, in which oxide of copper is used as a depolarising agent. The oxide, in powder, is placed in or on a sheet of copper or iron. The positive element is zinc, and the exciting liquid caustic potash. A zincate of potash is formed by the solution of the zinc. The cell is absolutely inactive when the circuit is open. When closed, the current is remarkably constant. According to Hospitalier, the electromotive force is 0·98 volt. It must of course be closed from the air, to prevent absorption of carbonic acid by the potash. The reduced copper is reoxidised by simple exposure to the air.

IN a series of studies on the copper voltameter, published in the *Repertorium der Physik* by Dr. H. Hammerl, the following conclusions are formulated:—1. The material condition of the surface of the electrode, that is to say, whether it is covered with a bright copper film or not, has no influence on the amount of the deposit. 2. The changes of concentration of the copper solution, brought about in the voltameter by the current itself, cannot be sufficiently prevented by stirring. 3. Heating the fluid to boiling causes the deposit to come down almost completely in the state of cuprous oxide: it is partially oxidised even at temperatures between 40° and 60° C. 4. The greatest permissible strength of current, for which the deposit may be safely assumed to be a measure of the current, is about 7 amperes per square decimetre of the cathode surface.

THE EVIDENCE FOR EVOLUTION IN THE HISTORY OF THE EXTINCT MAMMALIA[1]

THE subject to which I wish to call your attention this morning requires neither preface nor apology, as it is one with the discussion of which you are perfectly familiar. My object in bringing it before the general session of the Association was in view of the fact that you were all familiar with it in a general way, and that it probably interests the members of sections which do not pursue the special branch to which it refers, as well as those which do; also, since it has been brought before us in various public addresses for many years during the meetings of this Association, I thought it might be well to be introduced at this meeting of this Association, in order that we might not omit to have all the sides of this interesting question presented.

The interests which are involved in it are large: they are chiefly, however, of a mental and metaphysical character; they do not refer so much to industrial and practical interests, nor do they involve questions of applied science. They involve, however, questions of opinion, questions of belief, questions which affect human happiness, I venture to say, even more than questions of applied science; certainly, which affect the happiness of the higher grades of men and women more than food or clothing, because they relate to the states of our mind, explaining as they do the reasons of our relations to our fellow-beings and to all things by which we are surrounded, and the general system of the forces by which we are surrounded. So it has always appeared to me: hence I have selected the department of biology, and have taken a great interest in this aspect of it.

---

[1] A lecture by Prof. E. D. Cope of Philadelphia, given in genera session before the American Association for Advancement of Science at Minneapolis, August 20, 1883. Stenographically reported for *Science*.

The doctrine of evolution, as taught by the biologists of to-day, has several stages as grounds or parts of its presentation. First, the foundation principle is this: That the species of animals and of plants, the species of organic beings, as well as the various natural divisions into which these organic beings fall, have not always been as we see them to-day, but they have been produced by a process of change which has progressed from age to age through the influence of natural laws; that, therefore, the species which now exist are the descendants of other species which have existed heretofore, by the ordinary processes of reproduction; and that all the various structures of organic beings which make them what they are, and which compel them to act as they now act, are the result of gradual or sudden modifications and changes during the periods of geologic time. That is the first phase or aspect which meets the naturalist or biologist.

Another phase of the question relates to the origin itself of that life which is supposed to inhabit or possess organic beings. There is an hypothesis of evolution which derives this life from no-life, which derives vitality from non-vitality. That is another branch of the subject, to which I cannot devote much attention to-day. There is still another department of the subject, which relates to the origin of mind, and which derives the mental organisation of the higher animals, especially of man, from pre-existent types of mental organisation. This gives us a genealogy of mind, a history of the production or creation of mind, as it is now presented in its more complex aspects as a function of the human brain. This aspect of the subject is, of course, interesting, and upon that I can touch with more confidence than upon the question of the origin of life.

Coming now to the question of the origin of structures, we have by this time accumulated a vast number of facts which have been collated by laborious and faithful workers, in many countries and during many years; so that we can speak with a good deal of confidence on this subject also. As to the phenomena which meet the student of zoology and botany at every turn, I would merely repeat what every one knows—and I beg pardon of my biological friends for telling them a few well-known truths, for there may be those present who are not in the Biological Section—that the phenomena which meet the student of biology come under two leading classes: the one is the remarkable fidelity of species in reproducing their like. "Like produces like," is the old theorem, and is true in a great many cases; just as coins are struck from the die, just as castings are turned out from a common mould. It is one of the most wonderful phenomena of nature, that such complex organisms, consisting of so many parts, should be repeated from age to age, and from generation to generation, with such surprising fidelity and precision. This fact is the first that strikes the student of these sciences. The general impression of the ordinary person would be that these things must continue unchanged. When I began to study zoology and botany, I was remarkably surprised to find there was a science of which I had no conception, and that was this remarkable reproduction of types one after another in succession. After a man has had this idea thoroughly assimilated by his honest and conscientious studies, he will be again struck with another class of facts. He will find, not unfrequently, that this doctrine does not apply. He will find a series of facts which show that many individuals fail to coincide with their fellows precisely, the most remarkable variations and the most remarkable half-way attitudes and double-sided aspects occurring; and he will come to the conclusion, sooner or later, that like does not produce like with the same precision and fidelity with which he had supposed it did. So that we have these two classes of facts,—the one relating to, and expressing, the law of heredity; the other, which expresses the law of metamorphosis. I should not like to say which class of facts is the most numerously presented to the student. In the present fauna we find many groups of species and varieties before us; but how many species we have, how many genera we have, and families, we cannot definitely state. The more precise and exact a person is in his definition and in his analysis, the more definite his science becomes, and the more precise and scientific his work. It is a case of analysis and forms. What the scales are to the chemist and the physicist, the rule and measure are to the biologist. It is a question of dimension, it is a question of length and breadth and thickness, a question of curves, a question of crooked shapes or simple shapes,—rarely simple shapes, mostly crooked, generally bilateral. It requires that one should have a mechanical eye, and should have also something of an artistic eye to appreciate these forms, to measure them, and to be able to compare and weigh them.

Now, when we come to arrange our shapes and our measurements, we find, as I said before, a certain number of identities, and a certain number of variations. This question of variation is so common and so remarkable, that it becomes perfectly evident to the specialist in each department that like does not at all times produce like. It is perfectly clear, and I will venture the assertion that nearly all the biologists in this room will bear me witness, that variability is practically unlimited in its range, unlimited in the number of its examples, unlimited in the degree to which it extends. That is to say, the species vary by failing to retain certain characteristics, and generic and other characters are found to be absent or present in accordance with some law to be discussed further on.

I believe that this is the simplest mode of stating and explaining the law of variation: that some forms acquire something which their parents do not possess; and that those which acquire something additional have to pass through more numerous stages than those which have not acquired so much had themselves passed through.

Of course we are met with the opposite side of the case,—this law of heredity. We are told that the facts there are not accounted for in that way; that we cannot pass from one class of facts to the other class of facts; what we find in one class is not applicable to the other. Here is a question of rational processes, of ordinary reason. If the rules of chemistry are true in America, I imagine they are true in Australia and Africa, although I have not been there to see. If the law of gravitation is effective here, I do not need to go to Australia or New Zealand to ascertain whether it is true there. So, if we find in a group of animals a law sufficient to account for their creation, it is not necessary to know that others of their relatives have gone through a similar process. I am willing to allow the ordinary practical law of induction, the practical law of inference, to carry me over these gaps, over these interruptions. And I state the case in that way, because this is just where some people differ from me, and that is just where I say the simple question of rationality comes in. I cannot believe that nature's laws are so dissimilar, so irregular, so inexact, that those which we can see and understand in one place are not true in another; and that the question of geological likelihood is similar to the question of geographical likelihood. If a given process is true in one of the geological periods it is true in another; if it is true in one part of the world it is true in another; because I find interruptions in the series here, it does not follow that there need be interruptions clear through from age to age. The assumption is on the side of that man who asserts that transitions have not taken place between forms which are now distinct.

We are told that we find no sort of evidence of that transition in past geological periods; we are assured that such changes have not taken place; we are even assured that no such sign of such transition from one species to another has ever been observed,—a most astonishing assertion to make *to* a biologist, or *by* a biologist; and such persons have even the temerity to cite special cases, as between the wolf and the dog. Many of our domestic dogs are nothing but wolves, which have been modified by the hand of man to a very slight extent indeed. Many dogs, in fact nearly all dogs, are descendants of wild species of various countries, and are but slightly modified.

To take the question of the definition of species. Supposing we have several species well defined, say four or five. In the process of investigation we obtain a larger number of individuals, many of which betray characters which invalidate the definitions. It becomes necessary to unite the four or five species into one. And so then, because our system requires that we shall have accurate definitions (the whole basis of the system is definitions—you know the very comprehension of the subject requires definitions), we throw them all together, because we cannot define all the various special forms as we did before, until we have but one species. And the critic of the view of evolution tells us, "I told you so! There is but one species, after all. There is no such thing as connection between species; you never will find it." Now, how many discoveries of this kind will be necessary to convince the world that there are connections between species? How long are we to go on finding connecting links, and putting them together, as we have to do for the sake of the definition, and then be told that we have nevertheless no intermediate forms between species? The matter is too plain for further comment. We throw them together simply because our definitions require it. If we knew all the known individuals which have lived, we should have no species, we should have no genera. That is all there is of it. It is simply a question of a universal accretion of material and the collection of information. I do not believe that the well-defined groups will be found to run together, as we call it, in any one geological period, certainly in no one recent period. We recognise, however, that they diverge to a wonderful extent; one group has diverged at one period, and another one has become diversified in a different period; and so each one has its history, some beginning farther back than others, some reaching far back beyond the very beginning of the time when fossils could be preserved. I call attention to this view because it is a very easy matter for us to use words for the purpose of confusing the mind; for, next to the power of language to express clear ideas, is its power of expressing no ideas at all. As we all know, we can *say* many things which we cannot *think*. It is a very easy thing to say twice two is equal to six, but it is impossible to think it.

I would cite what I mean by variations of species in one of its phases: I would just mention a genus of snakes, Ophibolus, which is found in the United States. If we take the species of this snake genus as found in the Northern States, we have a good many species well defined. If we go to the Gulf States and examine our material, we see we have certain other species well defined, and they are very nicely defined and distinguished. If now we go to the Pacific coast, to Arizona and New Mexico, we shall find another set of species well defined indeed. If we take all these different types of our specimens of different localities together, our species, as the Germans say, all tumble together; definitions disappear, and we have to recognise, out of the preliminary list of thirteen or fourteen, only four or five. That is simply a case of the kind of fact with which every biologist is perfectly familiar.

When we come to the history of the extinct forms of life, it is perfectly true then that we cannot observe the process of descent in actual operation, because, forsooth, fossils are necessarily dead. We cannot perceive any activities because fossils have ceased to act. But if this doctrine be true we should get the series, if there be such a thing; and we do, as a matter of fact, find longer or shorter series of structures, series of organisms proceeding from one thing into another form, which are exactly as they ought to be, if this process of development by descent had taken place.

I am careful to say this, because it is literally true, as we all must admit, that the system must fall into some kind of order or other. You could not collect bottles, you could not collect old shoes, but you could make some kind of a serial order of them. There are no doubt characters, by which such and such shoes could be distinguished from other shoes, these bottles from other bottles; but it is also true that we have, in recent forms of life in zoology and botany, irrefragable proofs of the metamorphoses, and transformations, and changes of the species, in accordance with the doctrine which we commenced with.

We now come to the second chapter of our subject. With the assumption, as I take it, already satisfactorily proven, of species having changed over into others—in considering this matter of geological succession or biological succession, I bring you face to face with the nature and mode of the change, and hence we may get a glance, perhaps, at its laws.

I have on the board a sketch or table which represents the changes which took place in certain of the mammalia. I give you a summary of the kind of thing which we find in one of the branches of palæontology. I have here two figures, one representing a restoration, and the other an actual picture, of two extinct species that belong to the early Eocene period. One represents the ancestor of the horse line, Hyracotherium, which has four toes on his anterior feet, and three behind; and the other, a type of animal, Phenacodus, which antedated all the horse series, the elephant series, the hog, the rhinoceros, and all of the other series of hoofed animals. Each presents us with the primitive position in which they first come to our knowledge in the history of geological time.

I have also arranged here a series of some leading forms of the three principal epochs of the Mesozoic times, and six of the leading ones of the Tertiary time. I have added some dates to show you the time when the faunæ which are entombed in those beds were discovered in the course of our studies; and you will easily see how unsafe it is to say that any given type of life has never existed, and assert that such and such a form is unknown; and it is still more unsafe, I think, to assert that any given form of life properly defined, or that a specific intermediate form of life, will not be found. I think it is much safer to assert that such and such intermediate forms will be found. I have frequently had the pleasure of realising anticipations of this kind. I have asserted that certain types would be found, and they have been found. You will see that I attend to the matter of time closely, because there have been a great many things discovered in the last ten or fifteen years in this department. In these forms I give the date of the discovery of the fauna in which they are embraced.

Formation	No. of toes	Feet	Astragalus	Carpus and Tarsus	Ulno-radius	Superior Molars	Zygapophyses	Brain
Miocene ... ... Upper ... ... (Loup Fork)	1–1 2–2 3–3 4–4 (5–5)	Digitigrade (Plantigrade)	Grooved (Flat)	Interlocking (Opposite)	Faceted	4-tubercles, crested and cemented	Doubly involute Singly do.	Hemispheres larger, convoluted
Middle ... ... (John Day)	2–2 3–3 4–4	Digitigrade	Grooved	Interlocking	Faceted Smooth	4-tubercles, and crested	Singly involute Doubly do.	Hemispheres larger, convoluted
Lower ... ... (White River)	3–3 4–3 4–4	Digitigrade Plantigrade	Grooved	Interlocking	Smooth Faceted	4-tubercles, and crested	? Singly involute	Hemispheres small; and larger
Eocene ... ... Upper ... ... (Bridger)	3–3 4–3 4–5 5–5	(Digitigrade) Plantigrade	Grooved (Flat)	Opposite Interlocking	Smooth	4-tubercles 3-tubercles, and crested	Singly involute Plane	Hemispheres small
Middle ... ... (Wasatch)	4–3 4–5 5–5	Plantigrade (Digitigrade)	Flat (Grooved)	Opposite Interlocking	Smooth	4-tubercles 3-tubercles, a few crested	Plane Singly involute	Hemispheres small; mesencephalon sometimes exposed
Lower ... ... (Puerco)	5–5	Plantigrade	Flat	Opposite	Smooth	3-tubercles (4-tubercles), none crested	Plane	Mesencephalon exposed; hemisphere small and smoother

Here we have the White River fauna discovered in 1856; then we skip a considerable period of time, and the next one was in 1869, when the Cretaceous series was found. Six or seven Cretaceous faunæ have been found. Thus we have the *Bridger* fauna in 1870, the Wasatch fauna in 1874. Next we have, in 1877, the Equus beds and the fauna which they embrace, which also was found in 1878. The Permian fauna, which is one of the last, is 1879; and the last, the Puerco, which gives the oldest and ancestral types of the modern forms of mammalia, was only found in 1881. When I first commenced the study of this subject, about 1860, there were perhaps 250 species known.

There are now something near 2000, and we are augmenting them all the time. I have found many myself: if they were distributed through the days of the year I think in some years I should have had several every day. But the accessions to knowledge which are constantly being made make it unsafe to indulge in any prophecies that, because such and such things have not been found, therefore such and such things cannot be; for we find such and such things really have been and really are discovered.

The successive changes that we have in the mammalia have taken place in the feet, teeth, and brain, and the vertebral column. The parts which present us the greatest numbers of variations are those in which many parts are concerned, as in the limbs and feet. In the Lower Eocene (Puerco) the toes were 5-5. In the Loup Fork fauna some possess toes but 1-1. Prior to this period no such reduction was known, though in the Loup Fork fauna a very few species were 5-5. Through this entire series we have transitions steady and constant, from 5-5, to 4-5, to 4-4, to 4-3, to 3-3, to 2-2, to 1-1. In the Puerco period there was not a single mammal of any kind which had a good ankle-joint, which had an ankle-joint constructed as ankle-joints ought to be, with tongue and groove. The model ankle-joint is a tongue-and-groove arrangement. In this period they were all perfectly flat. As time passes on, we get them more and more grooved, until in the Loup Fork fauna and the White River fauna they are all grooved. In the sole of the foot, in the Puerco fauna, they are all flat; but in the Loup Fork fauna the sole of the foot is in the air, and the toes only are applied to the ground, with the exception of the line of monkeys, in which the feet have not become erect on the toes, and the elephant, in which the feet are nearly flat also, and the line of bears, where they are also flat. As regards the ungulation between the small bones of the palm and of the sole there is not a single instance in which the bones of the toes are locked in the Lower Eocene, as they are in the later and latest Tertiary.

When we come to the limbs, the species of the Puerco fauna have short legs. They have gradually lengthened out, and in the late periods they are nearly all relatively long.

(To be continued.)

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Dec. 13, 1883.—"On the Figure of Equilibrium of a Planet of Heterogeneous Density," by G. H. Darwin, F.R.S., Plumian Professor of Astronomy in the University of Cambridge.

If a rotating planet be formed of compressible fluid, the strata of equal pressure are of equal density, and the ellipticity of the strata increases from the centre outwards. Since it is supposed that the earth consolidated into its present form from a fluid or semi-fluid condition, the determination of the arrangement of internal density and of the law of ellipticity in such a planet is often called the problem of the figure of the earth. When the law of compressibility of the fluid is known, the laws of density and ellipticity are determinate, but the differential equations involved are of such complexity that only one solution of the problem is well known, viz. that associated with the names of Legendre and Laplace.[1]

In this solution the modulus of compressibility varies as the square of the density, but the assumption of this law appears to have been dictated more by the necessity of solving a certain differential equation than by physical considerations.

The comparison of the solution of the problem with the observed facts with regard to the earth may be made in several ways. The constant which determines the rate of the earth's precessional motion gives us information with regard to the arrangement of density in the interior, and the ellipticity of the surface is determined by geodesy and by the amount of a certain inequality in the moon's motion. Now, in order that the solution of the problem of the earth's figure may be satisfactory, the same arrangement of internal density must give the observed amounts both to the precessional constant and to the ellipticity of the surface.

Laplace's solution is highly satisfactory in this respect; and at the same time it makes the mean density of the whole earth about twice as great as the density of the surface stratum. The density of rock is about 2·8, and that of the whole earth is about 5·6.

In this state of our knowledge another solution of this celebrated problem possesses some interest, even if its results are not quite so satisfactory as those of Laplace's theory.

In the present paper such a solution is offered. The law of compressibility of the fluid is such, that the modulus varies as a power of the density, which power may range from negative infinity to $\frac{4}{3}$. When the power is zero, we have constant compressibility; and when the power is unity, we have the same law of compressibility as in a gas.

The solution is expressible in a far simpler algebraic form than that of Laplace, and it differs from his solution in placing a far larger proportion of the mass of the planet in the central regions.

It is remarkable that this solution affords for the case of the earth a correspondence between the precessional constant and the surface ellipticity equally good with that of Laplace. To obtain this correspondence we have to assume the compressibility of the fluid to be nearly constant.

The density of the surface layer appears however to be 3·7, and this is considerably greater than that of ordinary rocks. This result tells adversely to the acceptability of the proposed solution, but the discrepancy is not so serious as might appear at first sight. It appears from pendulum experiments on the Himalayan plateau and on the Andes, that there is a considerable deficiency of density underneath those great ranges. This would favour the view that our continents are a mere intumescence of the surface layers. In this case there must be a somewhat abrupt change in the law of density at only a few miles below the surface. The theory of the earth's figure can take no account of a sudden change of density on passing into a swollen superficial layer, and the value of the surface density to be used is that which is to be found immediately below the swollen part.

The author therefore points out that whilst the solution now offered cannot be held to be quite as satisfactory as that of Laplace, yet its inferiority is not of a kind to render altogether unacceptable the contention that it may be somewhere near the truth.

Linnean Society, December 20, 1883.—Alfred W. Bennett, M.A., in the chair.—Messrs. N. Cantley, W. Dobson, F. G. Smart, and Rev. R. Thom were elected Fellows of the Society —Mr. S. O. Ridley exhibited and made remarks on a series of 177 vertical sections of sponges collected in the neighbourhood of Point de Galle, Ceylon, by Dr. W. C. Ondaatje, F.L.S., and transmitted to England by him in letters. They are in most instances sufficient for the identification of the genera and some species.—Mr. F. Maule Campbell showed the web of a spider (*Tegenaria guyonii*) which had been spun in the centre of a pasteboard cylinder, the peculiarity being the manner in which the solid part of the web was medially swung, whereas in this species of spider it is more usually on the sides of objects.—A paper was read by Mr. F. O. Bower on the structure of the stem of *Rhynchopetalum montanum*. The plant is a native of Abyssinia, growing in districts 11,000 to 13,000 feet above the level of the sea. It differs from its ally Lobelias in being perennial. Internally it is succulent when young, but afterwards the surface becomes scarred as the leaves drop off, and exteriorly is hardened by a thick corky deposit. *Rhynchopetalum*, the author shows in detail, has certain peculiarities in the arrangement of the tissue of its leaf bundles, since the cortical system does not consist of branches of bundles of the leaf trace, but are cauline bundles, in this respect differing widely from such forms as *Lathyrus casuarina*, many *Begonias*, &c. *Rhynchopetalum*, moreover, has the cortical bundles running obliquely, and forming a regular four-sided meshed network related to the leaf bases and bundles of leaf trace. In these respects it approaches *Cycas*, in which latter the bundles of the accessory cortical system are not so regular and are almost vertically arranged. Some Cycads and *Rhynchopetalum* also agree in the exterior appearance of their stem, so that palæontologists might be deceived in their judgment if two well-preserved specimens were examined by them.—A communication was read on the auditory ossicles of *Rhytina stelleri* by Alban Doran. This was based on skeletons obtained by the *Vega* expedition, and shown at the late International Fisheries Exhibition by the Swedish Government. The author arrives at the conclusion that the malleus of *Rhytina* is larger than in *Manatus*, and therefore it is the largest and bulkiest malleus to be found in the whole section of the animal kingdom where such a bone exists, that in the characters of its body it resembles *Manatus* rather than *Halicore*, and that in the manubrium it differs from the other Sirenia, and is far more generalised. The incus is of the *Manatus* type, and so is the stapes, which is also the largest and bulkiest stapes to be found in any animal.—A paper on the organs of secretion in the Hypericaceæ, by Mr. J. R. Green, was read. He concludes (1) that the view advocated by Link, Martinet, and De Bary, of the lysigenous origin of the reservoirs of ethereal oil in these plants is the correct one; (2) that there exists in many parts of the plants a series of ducts or passages differing only slightly from these reservoirs, the differences being that they are not globular and isolated, but are generally connected more or less intimately with each other, and that their secretion is not a clear ethereal oil, but a viscid or resinous liquid, the points of agreement being those connected with their development and function; (3) that at least in some species there is also a series of schizogenous ducts confined to certain portions of the phloem; (4) that the dark glands which have been described are in intimate relationship with the fibrovascular system; (5) that the formation of resin and kindred secretions in these plants is confined to the parts where metabolism is active, and where there is a primary meristem. That all such parts give evidence of such formation with the exception of the roots.—A paper on the glands of *Coprosma baueriana*, by Mr. Walter Gardiner, was read. These glands are externally well developed and very typical. The so-called stipular body is placed immediately behind each leaf, and in the young condition the stipule arches over the leaf, and the glands with which it is provided secrete copiously a mucilaginous fluid, which bathes and surrounds the young leaf structure. As to the development of the glands, they arise as protrusions of the stipule parenchyma, which are covered by an epidermis. Each epidermal cell then rapidly grows out at right angles to the protuberance. In *Coprosma* the glands are situated on the sides of the stipules, but it more usually occurs in other genera that they are distributed over the inner face of the base of the stipular organ.—The last paper taken was on the development of starch grains in the laticiferous cells of the Euphorbiaceæ, by M. C. Potter. It is pointed out that while the discovery of the existence of starch-forming corpuscles had been made by Kruger, yet he had failed to interpret their function, which Mr. Potter's researches now fully prove in the case of the Euphorbiaceæ, where the development of rod or spindle-shaped grains of starch lying within cell protoplasm has been clearly demonstrated.

---

[1] The late M. Roche seems to have also solved the problem in 1848, and his paper is published in the *Memoirs of the Academy of Montpellier*.

Chemical Society, Dec. 6, 1883.—Dr. Perkin, president, in the chair.—The following gentlemen were elected Fellows:—F. A. Blair, T. J. Barr, C. J. Baker, L. Briant, R. G. Durrant, Kamchundra Datta, L. L. Garbutt, A. E. Harris, T. Hart, W. Irwin, S. Johnson, R. Jackson, H. C. Lee, W. H. Martin, C. E. Potter, B. M. K. Rogers, C. W. Stephens, P. H. Wright, H. A. Wetzel, and W. G. Whittam.—The following papers were read:—On the constitution of the fulminates, by E. Divers and M. Kawakita. When moist mercury fulminate is treated with much strong hydrochloric acid, hydroxyammonium chloride and hydrocyanic acid are formed; if the fulminate be dry, no prussic acid is formed. The carbon is completely converted into formic acid. No oxalic acid is produced.—Theory of the constitution of the fulminates, by E. Divers.—On Liebig's production of fulminating silver without the use of nitric acid, by E. Divers and M. Kawakita. When nitrous acid is passed into an alcoholic solution of nitrate of silver, crystals separate; these are not, as Liebig stated, fulminating silver, but nitrate of silver.—Note on the constitution of the fulminates, by H. E. Armstrong.—Experimental investigation on the value of iron sulphate as a manure for certain crops, by A. B. Griffiths. The author obtained from an experimental plot of land manured with ferrous sulphate fifty-six bushels of beans; a similar plot in its normal state gave thirty-five bushels. The ash of the plants also contained more iron and phosphoric acid in the first case.

Physical Society, December 8.—Prof. G. Carey Foster, in the chair.—New members:—Major McGregor, R.E., Mr. James Walker, M.A., Mr. W. B. Gregory, B.A.—Prof. Silvanus P. Thompson, D.Sc., read a paper on the static induction telephone as an instrument of research. The author had employed Dolbear's telephone in investigating the action of influence machines such as those of Holtz and Wimshurst or Toepler. This was done by holding the end of a wire (connected to one terminal of the telephone) near the electrified parts of the machine, for example the "carriers" in the Toepler apparatus. The carriers induced a change in the telephone, whose other terminal was to earth, as they passed, and the pitch of the note heard in the telephone increased with the speed at which the machine was driven. Useful results were obtained leading to modifications of some machines. The same telephone was also applied to the measurement of capacities of condensers arranged like the resistances of a Wheatstone balance, and the telephone taking the place of a galvanometer. For the "divided coil" of the balance Prof. Thompson substituted a double condenser, or rather two condensers, so joined that the earth-plates were separate, while the other plates were in one. This device was made from two glass tubes with tinfoil round their outsides and a brass tube sliding into both interiors in such a way that the relative capacities of the two condensers thus combined could be altered by sliding the tube between them. A modification of this plan was suggested by Mr. Starling, the author's assistant, which was analogous to Prof. Foster's arrangement of the Wheatstone balance, that is to say, six condensers were used, the two extra ones being included between the battery connections and the sliding tube. The battery was in this case an induction coil having no condenser, as a discontinuous current is necessary to give sounds. The author also showed that the Dolbear telephone could be used instead of the quadrant electrometer in such experiments as those of Mr. J. E. H. Gordon on specific inductive capacity. The author also showed how he had applied it to explore the equipotential surfaces round conductors charged statically by an induction current. With two wires from the terminals of a telephone silence is produced when both ends are on the same equipotential surfaces; and sounds when they are not.—Prof. Thompson then read a note on a new insulating stem. This consisted of a glass tube with one end blown into a flat foot, which was planted on the bottom of a glass bottle and cemented there by a little wax paraffin. The upper and open end of the tube served to hold the stems of brass plates, or other electrified bodies. Paraffin oil or strong sulphuric acid could be used in the bottom of the bottle. A cap of rubber or percha made to slide up the stem served as a dust cover.—Prof. Thompson next made a communication on the first law of electrostatics, and illustrated his remarks with experiments showing how a series of floating magnet poles of like name repelling one another tend to produce equal distribution of the poles. Prof. Thompson, arguing from the second law of electrostatics (inverse squares), sought to explain the first law in a rational manner, on the hypothesis of self-repelling molecules, which tend to uniform distribution. When there is a surplus in one part and a deficit in another, the molecules are urged towards each other, *i.e.* attract. This was shown by putting a surplus of floating magnets at one part of the basin. By the movements of these magnets when confined by barriers, and with surplus and deficit purposely made, the author imitated the effects of a Leyden jar, induction, a battery current, &c., the motions and arrangement of the poles illustrating the hypothetical behaviour of electricity. The author was led by the hypothesis to infer that either the ether is electricity, or that the ether is electrified, and the former seemed the simpler conclusion.—Dr. Monkman showed some experiments illustrating the attraction and repulsion of bodies in motion. The attraction of a light balanced body to a vibrating tuning-fork was shown; also the attraction between two disks of paper revolving parallel and in the same direction. The author showed that two smoke-rings travelling abreast in the same direction attracted each other, and that two paper rings revolving in the same direction close together attract, while if revolving in opposite directions they repel.—Mr. Walter Baily exhibited his new integrating anemometer in action by means of a small electric motor, which took the place of the Robinson cups. The apparatus sums up, or integrates, the wind velocities on the lines of the four cardinal points. An electric counter is attached.

PARIS

Academy of Sciences, December 17, 1883.—M. Blanchard, president, in the chair.—Preliminary report on the expedition of the *Talisman* to the Atlantic Ocean, by M. Alph. Milne-Edwards.—On the preparation and manner of employing artificially developed virus attenuated by heat, intended to be used in prophylactic inoculations against charbon, by M. A. Chauveau. —On the remarkable sunsets observed during the months of November and December, 1883, by M. P. de Gasparin. The author considers that these luminous effects cannot be due to falling stars, and must be referred to the solar light acting on an atmosphere charged with particles of matter whose nature has not yet been determined.—On the determination of elastic forces, by M. Fontaneau.—On the processes adopted by M. Mandon and M. Aman-Vigié in the treatment of vines affected by phylloxera, by M. F. Henneguy. The process of Dr. Mandon, which consists in saturating the sap with a solution of phenic acid, appears to have little or no effect on the parasite. That by M. Aman-Vigié, an injection of a mixture of vapours of sulphur and sulphuric acid into the ground, has been tried on too limited a scale to warrant any definite judgment as to its efficacy. but the experiments already made do not appear to have proved very beneficial, because the vapours of sulphuric acid do not penetrate to a sufficient depth into the ground, and evaporate too rapidly.—Observations of the Pons-Brooks comet made at the Paris Observatory with the bent equatorial, by M. Périgaud. —Observations of the planet 235 Carolina and of the Pons-Brooks comet made at the Paris Observatory (west equatoreal in the garden), by MM. Henry.—On the multipliers of linear differential equations, by M. Halphen.—On a point in the theory of elliptical functions, by M. Lipschitz.—On a theorem of M. Liouville in mathematical analysis, by M. Stieltjes. In continuation of his previous paper, the author here shows how the theory of elliptical functions leads to the theorem of M. Liouville.—On algebraic equations, by M. H. Poincaré.—Demonstration of the fundamental properties of the system of geodesic polar coordinates, by M. G. Ossian-Bonnet.—On a method of generating the ovals of Descartes proposed by Chasles in his "Aperçu Historique," by M. Maurice d'Ocagne.—On the measurement of the specific heats and variations of temperature of two bodies in contact, by M. Morisot.—On a practicable method available for the photometric comparison of the usual sources diversely coloured, by M. J. Macé de Lépinay.—On the influence of colour on the sensitiveness of the eye to different degrees of luminosity, by M. Aug. Charpentier.—Researches on the permanence of the solidification of superfused sulphur (continued), by M. D. Gernez.—Second note on chromic selenite; preparation of biselenite, by M. Ch. Taquet. The author has obtained a biselenite of chromium by the action of nitric acid on neutral selenite. It is almost insoluble in water, but soluble in acids, and decomposable by heat.—Note on the action of bromium on pilocarpine ($C_{22}H_{16}Az_2O_4$), by M. Chaasting.—On emetics of mucic and saccharic acids, by M. D. Klein.—Third note to serve as a contribution to the history of the formation of coal; genus *Arthropitus*, Gœppert, by M. B. Renault.—On the artificial reproduction of schistosity and slate layers, by M. Ed. Jannettaz.—Experiment relative to the mode of formation of bauxite and gypsum, by M. Stan. Meunier.—On the glaucous amphibolic schists of the island of Groix, by M. Barrois.—On an anorthite rock discovered at Saint Clément, Canton of Saint-Anthême (Puy-de-Dôme), by M. F. Gonnard.—On the fall of cosmic dust, by M. E. Young.—On the coincidence of the recent phenomenal after-glows with the passage of the cosmic meteors, by M. Chapel.

December 24, 1883.—M. Blanchard, president, in the chair. —The President announced the painful loss sustained by the Academy in the person of M. Yvon Villarceau, member of the Section for Geography and Navigation, who died after a short illness on December 23. Funeral orations on the deceased savant were pronounced by Col. Perrier in the name of the Academy, by M. Faye in the name of the Bureau of Longitudes, and by M. Tisserand in the name of the Paris Observatory.—Separation of gallium (continued): separation from terbium, ytterbium, and the earth provisionally called y_α by M. de Marignac, from scandium and fluor, by M. Lecoq de Boisbaudran.—Observations of the comet Pons-Brooks, made at the Observatory of Algiers by MM. Trépied and Rambaud.—Observations of the same comet made at the Lyons Observatory (Brunner equatorial of 0·160 metre), by M. Gonnessiat.—On a special development of the perturbing function

$$\frac{1}{\Delta^s} = \frac{1}{(r^2 - 2rr' \cos v + r'^2)^{\frac{s}{2}}},$$

by M. O. Backlund.—On the purely trigonometrical series connected with M. Linstedt's new solution of the problem of three bodies, by M. H. Poincaré.—On the generation of geometrical surfaces, by MM. J. S. and M. N. Vanecek.—On the gauging of galvanometers, by M. E. Ducretet.—Researches on the permanency of the solidification of superfused sulphur (continued); production of a new crystallised variety of sulphur, by M. D. Gernez.—On the decomposition undergone in the presence of water by the acid phosphates of the alkaline earthy bases, by M. A. Joly.—Determination of the neutralising heat for the fluorhydric acid of the alkaline and alkaline-earthy bases, by M. Guntz.—On the kreatines and kreatinines, fourth note, by M. E. Duvillier.—Action of ammoniacal gas on the nitrate of methyl, by MM. E. Duvillier and H. Malbot.—Researches on the compound oxygenised ammonias, by M. Reboul. — On some haloid derivatives of ethane, by M. L. Henry.—On the pathologic anatomy of the phlegmon, and especially on the seat of the bacteria in this affection, by M. Cornil.—On the species of Arctic mollusks found by the *Talisman* Expedition at great depths in the intertropical waters of the Atlantic Ocean, by M. P. Fischer.—On the morphology of the plumicole Sarcoptides, by MM. E. L. Trouessart and P. Mégnin.—On a rapid and economical method of treating vines affected by Peronospora, by M. Senderens.—On a parasitic Nematode of the common onion, by M. Joannes Chatin.—On the cultivation of beetroot and some other plants in solutions of organic substances in decomposition, by M. V. Jodin.—On the relations of the Serpentine rocks to saline substances, especially in the Pyrenees, by M. Dieulafait.—On a chlorosilicate of lime, by M. Le Chatelier.—Experimental researches on the velocity of aqueous or atmospheric currents capable of holding in suspense mineral particles, by M. J. Thoulet.—Note on the sunset glows recently reported to the Academy, by M. E. Marchand.—Observation of the after-glows witnessed at Valence on the evening of December 2, by M. P. du Boys.—Remarks on the sunsets observed at Rambouillet on the evenings of December 15 and 18, by M. A. Laugier.—Letter on the sunsets observed at Christiania towards the end of November, by M. Fearnley, director of the Christiania Observatory.

AMERICAN GEOLOGY

Twelfth Annual Report of the United States Geological and Geographical Survey of the Territories. In Two Parts, with Atlas of Maps, &c. By F. V. Hayden, U.S. Geologist. 8vo. (Washington: 1883.)

THERE is a singular fascination in American geology. Its features are as a whole so massive and colossal, their infinite detail so subordinated to breadth of effect, their presentation of the great elements of geological structure so grand, yet so simple and so clearly legible, that they may serve as types for elucidating the rest of the world. The progress of sound geology would assuredly have been more rapid had the science made its start in the Far West of America, rather than among the crumpled and broken rocks of Western Europe. Truths that have been gained on this side of the Atlantic by the laborious gathering together of a broken chain of evidence would have proclaimed themselves from thousands of plateaux, cañons, and mountain ranges, in language too plain to be mistaken. No doubt much has been gained by the mere oilsomeness of the search after the truth. A possession s more valued when it has been hard to obtain, and the qualities which its capture has called forth and strengthened could probably be educated in no other way. Nevertheless, no European geologist can visit these western regions without realizing more or less distinctly what an amount of time has been wasted here over questions about which there should never have been any discussion at all. This impression is renewed by every new geological memoir which brings to us fresh revelations of the scenery and structure of the Western Territories. It is especially deepened by a perusal of the volumes of which a brief notice will here be given.

It may be in the recollection of readers of NATURE hat after some inquiry and discussion it was discovered by the Congress of the United States that various independent Surveys, under different Government departments, had been engaged among the Western Territories, and, having no connexion with each other, had, to some extent, duplicated the mapping of the same ground; and hat at last in the summer of 1879 a law was passed whereby these various geological and topographical surveys were abolished, and a new single organization was created under the name of the "Geological Survey of the United States." One of the Surveys thus abolished was known as "the U. S. Geological and Geographical Survey of the Territories," under Dr. F. V. Hayden as Geologist in charge. The publications of this Survey comprised a voluminous series of annual Reports and Bulletins, quarto volumes of elaborate and well illustrated Memoirs, and Geological Maps and Sections. Many thousands of square miles of country had been xamined by the staff, and had been mapped and described in such a way as to lay out the broad features of wild regions for the first time, not only for the assistance f the geologist or geological surveyor who might afterwards care to fill in the details and improve the mapping, but for the guidance of future settlers in the far west, and f the Central authorities who have charge of the public lands. When, at the bidding of Congress, Dr. Hayden's Survey organization ceased to exist and his staff dispersed in search of other occupations, the work done in the year 1878 had not been published, while several important works were in progress. A small appropriation was granted to enable him to bring out his last Report and to complete other office-work of the Survey. This grant was exhausted in the summer of 1882, leaving five quarto volumes still unpublished though far advanced towards completion. These have been handed over to the Director of the Geological Survey, to be finished and published under his auspices. The final Annual Report, however, being the twelfth of the series, has at last been issued, the delay in its appearance having arisen from the scattering of the staff and their employment in other avocations, but partly perhaps (though he makes no mention of it) to the prolonged indisposition under which Dr. Hayden has been labouring ever since his retirement from official life.

Dr. Hayden's Report for 1878 is a most fitting termination to the series which it closes. It consists of two massive octavo volumes with an atlas of Maps and Panoramas, and is profusely illustrated with plates. It is of course impossible to give any adequate notice of this elaborate work within the limits permissible in these pages. But a mere outline of its contents may afford some idea of the nature and importance of this latest contribution to American Geology.

The first volume opens with a Prefatory Letter from Dr. Hayden himself, stating briefly the arrangement of the work under his supervision during the last year of its progress. One of his parties was charged with the primary triangulation of the entire area to be surveyed, and made satisfactory progress, among the Wind River and adjacent ranges westwards to Henry's Lake, where its operations were unfortunately cut short by Indians who crossing its trail, carried off all its animals and a portion of its outfit. Not far to the north lay the Yellowstone Park—an area perpetually exempted from settlement by special Act of Congress. That wild tract, surrounded by rugged mountains, formed a natural retreat for bands of hostile Indians when pursued by troops. Only the year before, the Nez Percés, retreating from General Howard, broke into the region, killing and plundering as they went. No wonder the surveyors should excuse any shortcomings in their work by pleading "that peculiar mental condition consequent on the uncertain and exaggerated rumours relative to the movements of the hostile Bannacks by whom the country was said to be overrun, but of whose presence we saw no more than the traces of some days' old trails." Next year, the writer of these lines, having previously heard similar wild rumours, passed over some of the same ground, but actually encountered an armed party, and will always remember the "peculiar mental condition," which the dust-cloud of the approaching red-skins awakened.

A second division of the staff made a detailed survey of the Yellowstone Park, obtaining materials for a Map of it on the scale of one inch to a mile. Mr. W. H. Holmes, attached to this party, had excellent opportunity for wielding that facile pencil to which geological science is so much indebted. Dr. A. C. Peale and Mr. Musbach made a detailed study of the thermal springs for which the region is now so famous.

A third division surveyed the previously little known but magnificent snowy range of the Wind River Mountains, in which three true glaciers were observed—the first known to occur east of the Coast Range of the Pacific border.

The Report of these various surveys and of palæontological and natural history researches connected with previous explorations is divided into two parts. Taking the second part first, we have a stout volume of some 500 pages with 80 plates, besides figures, maps, and sections entirely devoted to the Yellowstone Park. A good deal has been written on the wonders of this region, chiefly in previous Reports of Dr. Hayden's Surveys, and sometimes in considerable detail, as, in Professor Comstock's Report, accompanying Captain Jones' Reconnaissance published in 1875. But no such minutely circumstantial narrative has ever appeared as that now issued.

An exceedingly erroneous general impression is conveyed by the word "Park" which has been applied to this region and which has received the sanction of an Act of Congress. The tract comprises an area of upwards of 3500 square miles, most of it being forest covered and of a rugged mountainous character. Some of the peaks rise to between 10,000 and 11,000 feet above the sea. Between the lower ridges, open glades of park-like woodlands make one half forget for a while the great altitude and remoteness of the region, till the true character of the place is recalled by some pine-trunk deeply scored by a passing bear or by a herd of "antelopes" or an occasional "elk" scampering across the sunshine into the gloom and silence of the surrounding forest. Through this region, the Yellowstone River and its tributaries, draining a series of lakes, flows northward till it enters a profound cañon in which, at times unseen and unheard, it chafes the feet of volcanic precipices until, emerging amid a series of glacier moraines, it passes out of the "Park" into the Territory of Montana.

The Monograph of this deeply interesting region now published by Dr. Hayden is composed of three unequal sections. The first of these, by Mr. W. H. Holmes, treats of the general geology. It is no disparagement to the author to say that the most valuable part of his Report is to be found in his admirable sketches. He adds some interesting particulars, indeed, to what was already known of the geology of the district. For example he has worked out in greater detail the structure of Cinnabar Mountain which forms so striking a feature in the ascent of the Yellowstone above the second cañon, likewise the geology of the remarkable volcanic plateau of which one sees a section from the camping ground at the Mammoth Hot Springs. The beautiful unconformability under the sheet of rhyolite which forms so impressive a feature in that landscape stands out with admirable clearness in Mr. Holmes' drawings. Evidence is supplied of the diminution of the Yellowstone Lake. A reference, tantalizingly brief, to the interesting glacial problems of the district concludes this short Report. The author was too well and busily employed with his pencil to find time for much independent geological observation. But it is matter for hearty congratulation that before he was moved away into the vaster domain of the Grand Cañons of the Colorado, where he has since done such service to the United States Geological Survey, he was enabled to spend long enough time in the Yellowstone region to produce the series of pictoral illustrations which enric Dr. Hayden's final Report. His trained eye and powe of rapid and accurate sketching greatly contributed to th perfection of the map of the Park.

The second and by much the longest section of the book is devoted to the Hot Springs of the Yellowstone Park, and is from the pen of Dr. A. C. Peale, who spent about two months in the district making detailed observations of the geysers and other thermal waters. He describes more than 2000 springs and seventy-one geysers, and illustrates his descriptions with so numerous a series of plates that every minute detail and variety of form in the geysers and sinter accumulations is vividly brought under the eye. Dr. Hayden justly remarks that this preliminary work ought never again to be necessary. Short of an actual inspection of the geysers and basins themselves, nothing could give a clearer idea than these plates do of the extraordinary forms assumed by the deposits from the thermal waters. The strange coralloid and sponge-like aggregations are excellently depicted in lithographs which have obviously been reproduced from photographs. Dr. Peale's Monograph consists of three parts, the first devoted to a description of the geysers and thermal springs; the second to an account of the principal geyser regions of the world for purposes of comparison; the third to thermo-hydrology, in which he discusses the general characters of thermal waters, their chemistry and deposits, and the theories of geyser action. The premature disbanding of the Survey prevented the completion of this essay on the scale originally intended. But Dr. Peale may be congratulated on having made a most useful addition to the literature of the subject. Not the least of its merits is the copious bibliography which is given in an Appendix.

The third section of the volume, by that able cartographer Mr. H. Gannet, deals with the topography, and gives an interesting *résumé* of the various reconnaissances and surveys which have resulted in the present detailed map of the Yellowstone Park.

The other volume, forming Part I. of the Report for 1878 is divided into two sections. One of these, relating to geology and palæontology, contains a series of Reports by Dr. C. A. White on the invertebrate palæontology of the Western States and Territories from the Carboniferous to the Tertiary rocks, and is accompanied by forty-two Plates of Fossils. Some sections have a special interest, in particular that in which the author discusses the fossils of the much disputed Laramie group, and sustains his previously expressed opinion that this group should be regarded as transitional between the Cretaceous and Eocene formations of the West. The abrupt cessation of the Survey, by depriving Dr. White of an opportunity of completing some of his work by further collection, has materially crippled him in the preparation of these further contributions to a subject which he has already done so much to elucidate.

Mr. Orestes St. John supplies a report on the Wind River District Basin, and Mr. Scudder reprints with additions and alterations the report on the Tertiary Lake-basin of Florissant, Colorado, which has already appeared in the Bulletin of the Survey, and which made known the extraordinary abundance of insect remains preserved in the lacustrine deposits of that locality.

The second section of the volume is devoted to Zoology, and consists of two Reports—one of them an invaluable monograph by Mr. A. S. Packard, jun., on Phyllopod Crustacea, recent and fossil, illustrated with thirty-nine plates and a coloured map showing the zoological provinces of North America. This memoir will be welcomed by all who take interest in the investigation of genealogies and of the history of distribution in the animal kingdom. Dr. R. W. Shufeldt concludes the volume with an essay on the osteology of various American Birds, likewise copiously illustrated with woodcuts and with lithograph plates.

From this outline it will be seen how well Dr. Hayden has sustained to the last the character of the Survey under his charge. During his tenure of office he proved himself to be endowed with rare powers of organization and administration and to possess wide views of the scope of a survey which, like his, was to break ground for the first time in new and unknown territories. He might have been simply an explorer, anxious to find out the sources of rivers, the positions of passes, the heights of peaks, and the trend of mountain-ranges. He might have been a mere geologist, desirous of adding some thousand miles of new area to formations already known or of discovering formations such as have no precise parallel elsewhere. He might have been only a topographer, caring chiefly for the accuracy of his triangulations and levellings. He might have been a botanist or zoologist, eager to add new species to the known flora and fauna of the earth's surface. In one sense Dr. Hayden was none of these: in another sense he combined the functions of them all. In later years his executive duties appear to have left him little opportunity for carrying on original research himself. But he had sympathy with all the pursuits just named, and had the faculty of choosing good men for prosecuting them. He had force of character enough to succeed in battling his way and getting his appropriations from Congress, and he had the perseverance to press forward his operations, keeping his fellow-labourers together and publishing with their aid a series of volumes of which the United States may well be proud.

The consolidation of the various Surveys under one organization was an inevitable and entirely justifiable step on the part of Congress, and the United States Geological Survey could not be under more energetic and skilful direction than that of its present estimable chief, Major Powell, with the cooperation of such leaders in geological enterprise as Mr. Gilbert, Captain Dutton, and their colleagues. Nevertheless, it may be permitted to a geologist on this side of the Atlantic, who looks disinterestedly but not unsympathetically upon the progress of events on the other side, to express his regret that it should not have been possible to find a place where scope might have been afforded for the talents of one who had done such good service to geology as Dr. F. V. Hayden.

ARCH. GEIKIE

OUR BOOK SHELF

Attraction et Gravitation d'après Newton. Par Mme. Clémence Royer. Extracted from the Review "*Philosophie positive.*" Pp. 23. (Paris, 1883.)

IT is very surprising to find what is, in most other respects, a really well-written and able dissertation on the question of *action at a distance* marred at the very outset by an almost inexplicable blunder.

Madame Royer has evidently read much, and lays down with great clearness the distinction between Newton's Theory of *Gravitation* as a mode of grouping together under one simple law the whole phenomena of physical astronomy, and the assumption handed down from old Greece, of a mutual *attraction* exerted upon one another by any two portions of matter. She shows that Newton everywhere expresses himself in the most explicit terms against the notion of distance-action. But she also points out the curious distinction between Newton in the *Principia*, the pure mathematician and physicist, who constructs no hypotheses and declares that the mode in which gravitation is produced is one which he has not been able to discover from the phenomena themselves; and Newton in his *Optics*, the bold speculator, who discusses the possible characteristics and properties of the medium by which gravitation may be produced.

This is, on the whole, so well done that we are positively amazed to find the all-important property of matter, *Inertia*, absolutely and entirely ignored. From a psychological point of view, the following remarks, by such a writer as Madame Royer shows herself to be, are of the very highest interest and curiosity:—

> "Qu'est ce en effet que la notion de *masse*, si ce n'est celle d'un corps déjà considéré comme pesant? Un corps sans pesanteur serait-il une masse? en aurait-il les propriétés mécaniques? Une masse, supposée absolument isolée dans l'espace, aurait-elle un poids? Evidemment non, puisque le poids ne naît que des rapports de grandeur et de distance des masses. Dire que le poids ou la masse est proportionnel à la quantité de matière ou de substance, c'est affirmer une chose que nous ne savons pas, que nous ne pouvons absolument savoir d'aucune manière. Tout ce que nous savons c'est que, considérant des corps déjà pesants, en vertu de leurs relations de quantité et de distance, leur pesanteur croît en raison de ces quantités et en raison inverse de ces distances, sans que leurs quantités, comme matière, soient altérées, de façon que des masses doubles ont une tendance deux fois plus forte à tomber l'une vers l'autre, ce qui fait qu'elles s'approchent en réalité avec la même vitesse (*sic*), et que si leur distance devient moitié moindre, elles s'approchent quatre fois plus vite l'une de l'autre.
>
> "Mais comme l'unique moyen que nous ayons de mesurer la grandeur de ces masses est de les peser, nous restons dans l'impossibilité absolue de dire si des masses de même poids, en même relation de distance avec d'autres masses pesantes, contiennent, oui ou non, la même quantité de matière."

Evidently Madame Royer, in reading the *Principia*, has failed to notice, not only the definition of *Vis insita* but also, those important pendulum experiments by which Newton satisfied himself of the exact proportionality of weights to masses, in any one place. Here we see, in no doubtful manner, the evil effects of an education in which athletics have no part. No one, man or woman, who has had experience of Indian clubs or of dumb-bells, could for a moment doubt that we have another mode of distinguishing mass, besides weighing.

Electrotechnisches Jahrbuch von der Electrotechnischen Gesellschaft in Frankfurt am Main. (1883.)

ALL over Germany are springing up electrotechnical societies, in emulation of those in Berlin and Vienna, fulfilling a kindred part to that played in Great Britain by the much older Society of Telegraph Engineers and Electricians. The volume published by the Frankfort Society—the first of its *Proceedings*—contains several papers of interest. Amongst these may be noticed two by Dr. Th. Stein of Frankfort, on the measurement of small intervals of time by the photographic electric method; and on certain modern electro-chirurgical apparatus, especially modifications of the influence-machine of Holtz. In the first of these papers Dr. Stein describes an apparatus for photographing the pulsations of the heart, &c., as conveyed by a Marey's tambour to an apparatus which at the same time causes a record from an automatic tuning-fork interrupter to be imprinted side by side on the photographic plate. In Dr. Stein's second paper, he describes the use of a small Deprez electromotor to drive a small fan, by which warm, dry air is caused to circulate round a Holtz machine, which by this means is always ready for action. In some historical notes by Herr Holthof, dealing with the early stages of telegraphy, there comes out the interesting point that, so early as 1854, an important improvement had been made in the suggestion of Bourseul for an electric telephone. An anonymous writer, signing himself "L." in the pages of "Didaskalia," gave in that year, under the title of "Elektrische Telephonie," an account of Bourseul's crude notion, and added something not to be found in Bourseul's suggestion, namely, the use of an electromagnet in the receiver to actuate the disk of thin metal to which the listener was to apply his ear; the description of the instrument—which, it seems, never reached anything beyond an anonymous suggestion—reads like a description of a Bell telephone, of which it is a remarkable foreshadowing. It is remarkable that Reis, who was at that time resident in Frankfort, should, when using an electromagnet in his subsequently invented telephone, have stopped short of the use of a disk in his receiver in place of the bar armature he employed. It is pretty clear he did not know of "L.'s" suggestion. The remainder of the papers in the "Year-book" deal chiefly with telegraphic and fire-alarm apparatus. The Frankfort Society is to be congratulated on the value of the papers communicated to it during its short existence.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

What are the Saccopharyngoid Fishes?

In December of last year M. Vaillant communicated to the French Academy of Sciences a notice of a remarkable deep sea fish, to which he gave the name *Eurypharynx pelecanoides*. He was in great doubt as to the relations of this form, but concluded that "of all fishes it is to *Malacosteus niger*," placed in the family Scopelidæ by zoologists, that he was most inclined to approximate the new type. Five specimens of a nearly related form, to which Mr. J. A. Ryder and myself have given the name *Gastrostomus bairdii*, were obtained by the United States Fish Commission steamer *Albatross*, in the summer and autumn of the present year. The largest of these specimens is nearly two feet long, and an anatomical investigation reveals some very remarkable peculiarities of structure, which have caused Mr. Ryder and myself to differentiate the two forms, Gastrostomus and Eurypharnyx, in a distinct order of fishes to which we have given the name Lyomeri.

The Lyomeri are fishes with five branchial arches (none modified as branchiostegal or pharyngeal) far behind the skull; an imperfectly ossified cranium, deficient especially in nasal and vomerine elements, articulating with the first vertebra by a basioccipital condyle alone; with only two cephalic arches, both freely movable, (1) an anterior dentigerous one, the palatine, and (2) the suspensorial, consisting of the hyomandibular and quadrate bones; without opercular elements; without maxillary bones, or distinct posterior bony elements to the mandible, with the scapular arch imperfect (limited to a single cartilaginous plate) and remote from the skull; and with separately ossified but imperfect vertebræ. Whether other than the two genera mentioned, Eurypharynx and Gastrostomus, belong to this order is not entirely certain, but there is little doubt, in the opinion of Mr. Ryder and myself, that the family Saccopharyngidæ also belongs to the order, and it is for the purpose of calling attention to this doubtful and still little known type, that in behalf of Mr. Ryder and myself I address the present communication. No satisfactory information has been given as to the Saccopharyngidæ, except by Dr. Mitchill in 1824, and by Dr. Harwood in the *Philosophical Transactions* for 1827. The plate published in the volume cited represents the head of Ophiognathus with the mouth closed as well as open, and the differences in the relation of the posterior angles of the mouth to the axis indicate that Ophiognathus (as well as Saccopharynx) has a movable suspensorium, and would therefore exhibit the Lyomerous peculiarity of structure. It appears from Dr. Günther's "Catalogue of the Fishes in the British Museum" (vol. viii. p. 22), that in 1870 there were two specimens of a Saccopharyngoid fish—probably the *Ophiognathus ampullaceus*—in the British collection. (It is possible that the so-called young mentioned in the Catalogue may be a Eurypharyngoid.) The question whether that species belongs to the Lyomeri can therefore be readily settled negatively or affirmatively. Assuming that the family Saccopharyngidæ belongs to the order, the two families would apparently be distinguishable as follows:—

The Eurypharyngidæ are Lyomeri with the branchio-anal portion much shorter than the rostro-branchial; with the tail very elongated and moderately attenuated backwards; the head flat above and with a transverse rostral margin, at the outer angles of which the eyes are exposed; with the palatine jaws excessively elongated backwards and the upper parallel, and closing against each other as far as the articulation of the two suspensorial bones; with minute teeth on both jaws; the dorsal and anal fins well developed, and continued nearly to the end of the tail, and with minute narrow pectoral fins.

The Saccopharyngidæ appear to be Lyomeri with the branchio-anal portion much longer than the rostro-branchial; the tail excessively elongated and attenuated; the cranium unknown; the eyes antero-lateral; with the palatine bones moderately extended backwards (in comparison with the Eurypharyngidæ), and apparently not closable against each other; with enlarged teeth in one or both jaws; with the dorsal and anal fins feebly developed, and with pectorals small but broad. Saccopharynx is considered by Dr. Günther to consist of "deep-sea congers," but evidently it is not at all related to the congers or any other allied fishes.

I can assure English naturalists that no type of fishes will more fully reward investigation than the Saccopharyngidæ, and it is to be hoped that some master of applied anatomy, like Profs. Huxley or Lankester, may deem an examination of the specimens in the British Museum worthy of their attention. A few of the many remarkable peculiarities of organisation of the type have been described in an article "On the Anatomy and Relations of the Eurypharyngidæ," by Theodore Gill and John A. Ryder, in the *Proceedings* of the United States National Museum for 1883 (pp. 262-273), and a full monograph will appear later. May we hope for information respecting Saccopharynx in time to correlate it with that on Gastrostomus? Theo. Gill

Cosmos Club, Washington, December 18, 1883

The Mildness of the Season

As the flowering of plants at this time of the year is perhaps the best indication of the mildness of the season, I send you a list of the plants from which I and a friend gathered one or more flowers on the 24th and 26th inst. I have given the list of each day's gathering separately. Those on the 24th were gathered between this city and Hinton Charterhouse, once noted for its Carthusian monastery. Those of the 26th were gathered between Bath and Bradford-on-Avon, a very old town which contains the remains of a Saxon church and one of the finest tithe barns in England. Viator

Bath, December 27, 1883

List of Plants from which Flowers were gathered on December 24

Draba verna (Spring Whitlow Grass)
Primula acaulis (Primrose)
Veronica officinalis (Com. Speedwell)
Bellis perennis (Daisy)
Centaurea scabiosa (Greater Knapweed)
Ulex europæus (Com. Furze)
Achillea millefolium (Com. Yarrow)
Crepis virens (Smooth Hawk's Beard)
Lamium album (White Deadnettle)
Fragaria vesca (Wood Strawberry)

Gathered on December 26

Ranunculus repens (Creeping Crowfoot)
Cheiranthus chieri (Com. Wallflower)

Cerastium semidecandrum (Little Mouse-Ear Chickweed)
,, *triviale* (Lesser do.)
Arenaria tenuifolia (Fine leaved Sandwort)
Pimpinella saxifraga (Com. Burnet Saxifrage)
Pastinaca sativa (Wild Parsnip)
Torilis anthriscus (Upright Hedge Parsley)
Senecio vulgaris (Com. Groundsel)
,, *sylvaticus* (Mountain do.)
Crepis virens (Smooth Hawk's Beard)
Hypochæris radicata (Long-rooted Cat's Ear)
Taraxacum dens-leonis (Dandelion)
Veronica hederifolia (Ivy-leaved Speedwell)
,, *polita* (Gray Procumbent do.)
,, *agrestis* (Green do. do.)
Lamium purpureum (Red Deadnettle)
,, *album* (White do.)
Rumex crispus (Curled Dock)

River Thames—Abnormal High Tides

In a letter in Nature of November 2, 1882 (p. 6), I gave a review of exceptional tides from 1860, and attempted to trace the causes thereof; it appeared that from 1860 to 1868 inclusive the computed maximum rise above "Trinity Standard" of high water for spring tides was 6 inches, and the actual range excess was 3 feet 6 inches above that standard.

From 1869 to 1882 the greatest computed elevation at high water was 2 feet 1 inch, and the maximum rise 5 feet above "Trinity" at Westminster, viz. on January 18, 1881, and again on October 28, 1882, the same height was attained—in each case resultant on a great north-east gale. On November 14, 1882, the afternoon tide marked 2 feet 5 inches above "Trinity," or 2 feet 4 inches above computed height—resultant again on a north-north-east gale. Since then, during the last thirteen months, there have been no very exceptional tides until last springs.

The following abstract table gives the more salient results for the present year:—

High Waters referred to "Trinity"

[1] A gale. [2] A great gale.

It will be observed that in the majority of cases northerly winds accompany or have preceded the exceptionally high tides; also how a great westerly gale blowing down the river depresses the range of tide. The most remarkable result is that attendant on the great gale of the 12th inst. during last springs, for although high water level was less by 18 inches than in January, 1881, and October, 1882, it was exceptional for its great rise over the computed elevation, being no less than 3 feet 11 inches above the height denoted in the Admiralty tide tables with the reservation before named in my former letter, that the computed heights are for London Bridge. The high water of October 28, 1882, was 3 feet 4 inches above computed height; but the very remarkable tide of January 18, 1881, was actually 5 feet above the estimated range, which was only level with "Trinity Standard." The afternoon tide of Sunday, the 16th inst., was also, it will be seen, very much increased by the northerly gale then prevailing. J. B. Redman

Deafness in White Cats

Referring to the note in your issue of December 13 (p. 164), by Mr. Lawson Tait, on "Deafness in White Cats," I should like to state, if my remarks may not be out of date, that my father kept a breed of deaf white cats over several years; and on making an inquiry regarding these cats of my brother, who now lives in Reading, but who at that time was resident with my father on a farm in North Hampshire, he informs me that the deaf cats were all white with blue eyes, with one single exception, and that one refers to an aged mother who was named "Deaf," on account of her infirmity, and who had eyes of different colours, the one being "red," or pink, as seen in white rabbits, and the other blue. So remarkable was the appearance of this cat that the eyes often attracted the attention of visitors, and my brother has more than once related to me a circumstance which I should not mention here, save that it so thoroughly bears on this question as one of fact. On one occasion a neighbour, remarking on the ocular peculiarities of this cat, elicited from my father the jocular reply that "she had one eye for the rats, and another for the mice." My brother further states that these deaf cats were all females, and that the breed was preserved on account of its furnishing "good mousers." I apprehend that this characteristic may in some measure be attributed to the character of the eyes enabling the animals to see better in obscure light. Males were not preserved, because they became rovers and destroyed the game. When any of the offspring were pied, or otherwise coloured, they were not deaf. Bearing on this, and evidently referable to my brother's early associations, he once observed, in his walks round Reading, a white cat with blue eyes sitting at a cottage door, and on inquiring he found that the animal was deaf; but he made no observation as to whether it was male or female. Joseph Stevens

Teaching Animals to Converse

I have read with interest Sir John Lubbock's communication (p. 216), but I would like to know whether any precautions were taken to find out whether "Van" selected the right card by his sense of sight or by scent? This could have been easily done by changing the card for a facsimile which had not been previously scented. A more thorough test would be to employ a set of cards with "Food" written on one side of each and some other word on the other, then putting the cards in cases with an opening exposing one word only. The cards could then be put in a row and be kept in the same relative position, the changes for the experiments being made by turning the cards in their cases. Would it not be simpler to commence with drawings on the cards instead of words. For instance, a saucer or biscuit for "Food," a bone for "Bone," a hat for "Out," &c.?

On the Absence of Earthworms from the Prairies of the Canadian North-West

An incidental allusion is made by Mr. Christy in Nature of the 3rd inst. (p. 213) to Darwin's statement that earthworms "abound in Iceland." In 1881 I spent several weeks in that island, and had occasion many times to search for worms as a bait for trout and char around Thingvalla, Ori, the Sog River, &c., and could not obtain them except near the farmhouses—which are at great distances from each other—and absent altogether from the interior of Iceland, which is uninhabited and a desert. Richard M. Barrington

Merrifield's "Treatise on Navigation"

I beg to thank your reviewer of my book for the suggestions he has made in Nature of December 20 (p. 169), and should like to point out to him that he must have overlooked some remarks contained therein, when he says:—

"We regret that Mr. Merrifield has omitted from the chapter on Traverse Sailing the warning given by Raper, that, especially in high latitudes, the difference of longitude should be found on each course," &c., by Mercator's sailing.

Will you kindly allow me to remark that I mention this twice in my book? First, on pp. 88, 89 I say, "Middle-latitude sailing should not be used in (*a*) high latitudes; (*b*) when the difference of latitude is great; and (c) when the two places under consideration are on different sides of the Equator. In these cases Mercator's sailing should be used." And again, on p. 104, when speaking of a ship's journal (which I considered the right place to introduce it), I give this caution:—

"As longitude by inspection depends on the middle latitude, the cases in which it should not be used as explained under middle-latitude sailing should be attended to: and if the latitude be high, or the distance made good be great on a small course, then correct longitude can only be obtained by finding the position of the ship by Mercator's sailing on every change of course."

JOHN MERRIFIELD

Navigation School, Plymouth, December 22, 1883

[I WAS, of course, aware of the existence of the paragraphs mentioned by Mr. Merrifield, but they do not seem to meet the point raised, viz. that no notice was taken in the chapter on Traverse Sailing of the necessity of finding the difference of longitude on each course in high latitudes, although the subject is incidentally referred to at p. 104. There will doubtless always be differences of opinion between the writer and reviewer of a book, but it seems to me that, in teaching, the theory should be unassailable. Whether in practice it is necessary to apply all the corrections required should be left to the judgment of the practitioner. Mr. Merrifield has reversed this order, having omitted certain rules from the instructions on Traverse Sailing, but mentioned them casually in a paragraph preceding the copy of the log.—THE REVIEWER.]

AN AMERICAN ROTHAMSTED

HALF a century has elapsed since Sir John Lawes commenced at Rothamsted Park, in Hertfordshire, the unique series of experiments the results of which have produced so salutary an effect on agricultural practice. The inquiries were at the outset restricted to determining the influences of various kinds of manures, and these led to the institution, in the year 1843, of systematic field experiments which are still in progress. Wheat and barley have been grown on the same land for forty-one consecutive years, oats for twelve years, turnips for thirty years, potatoes for nine years, meadow herbage for twenty-eight years, while beans, clover, sugar-beets, and mangel-wurzel have likewise been grown more or less continuously, and all under the varied influences of the different manurial agents. The influence of soils and manures on the composition of crops, the relations of botanical characteristics to the soil and to manures, the physical and chemical properties of the soils themselves, the transpiration of water by plants, the question as to whether plants assimilate free nitrogen, the composition of rain and drainage waters,—these are some of the chief problems which have been the subjects of research. Not less noteworthy are the experiments which have been made with animals, such as the determination of the relation of quantity and kind of food consumed to increase in live weight, the proportion and relative development of the different organs of farm animals, the composition of the animals in different conditions as to age and fatness, the composition of the solid and liquid excreta in relation to that of the food consumed, and the composition of the ash of animals in different conditions and variously fed.

Valuable and highly appreciated as are the many published results of the Rothamsted researches, yet their significance could not fail to be greatly enhanced were it possible to compare them with similar experiments carried on elsewhere. But the efficient equipment of an agricultural experiment station like that at Rothamsted is a very costly affair, and, unless State aid can be relied upon, it can hardly be undertaken save through the munificence of private individuals. The splendid example set by the founder of the Rothamsted station in this country has stimulated an American gentleman to establish in the State of New York an experimental farm which is already well on the way towards becoming another Rothamsted. The credit of this enterprise is due to Mr. Lawson Valentine, who thereby realises "a long-cherished plan for doing something towards the progress of American agriculture," and at the same time providing a pleasant country home conveniently near his place of business in New York City.

Houghton Farm, Orange County, is within two hours' railway journey of New York City, and occupies an area of 600 acres. In the summer of 1879 the proprietor secured the services of Dr. Manly Miles as director of the projected experiments, and after a period of eighteen months, during which the fields were laid out and drained, the experiments were begun. Since the summer of 1881 the experimental work has been carried on as a distinct department, quite separate from that of the farm proper on the one hand, and from that of the residential portion of the estate on the other. Thus the present plans as to Houghton Farm are, in the words of the proprietor, the following:—1. That the farming operations be carried on in accordance with the best known methods, and under the best possible organisation and management, with a view to educating and enlightening others by furnishing valuable examples and results in practical agriculture. 2. That there be a scientific department devoted to agricultural investigation and experiment, and that such department be of the highest order, so as to command the respect, interest, and co operation of the leading scientific minds of this and other countries. 3. That Houghton Farm be a comfortable, healthful, and attractive home for the family of its proprietor, and afford large hospitality for friends and guests.

Two distinct though closely related and parallel lines of investigation are recognised. Firstly, the purely scientific work of the laboratory to gain a knowledge of the elements of animal and vegetable nutrition, and of their relations under known definite conditions. Secondly, accurate and well planned experiments in the feeding of animals and in the growth of crops to answer the various practical questions that arise in the management of the farm, and to determine the agricultural value of the facts and theories that are presented as the result of purely scientific investigations. Experiments under this second head demand, on the part of those who conduct them, an extended knowledge of practical farming, as well as the trained skill and ability for original investigations that are required in researches in pure science.

As the system of growing the same kind of crop on the same land for a continuous series of years, in the manner followed at Rothamsted, appears to be the only one that can be relied upon to give consistent and trustworthy results, this method has been adopted at Houghton Farm. But besides wheat, barley, and oats, the staple American cereal, Indian corn, forms the subject of a special series of experiments. Indian corn is successfully cultivated over a very wide area; it much exceeds in aggregate value any other crop grown in the United States; it is of great importance as a cleaning crop; and the large amount of cattle food of good quality it is capable of yielding, together with the value of the manure produced per acre when it is fed on the farm, all point to this crop as the one a series of systematic experiments upon the cultivation of which will yield results of greater practical interest to American farmers than will experiments with any other field crop.

The first report on the experiments with Indian corn has already been published, with considerable elaboration of detail. Some interesting results have been established, particularly those on the influence of drainage, on the employment of barnyard manure, and on the character and quality of the grain.

Prof. D. P. Penhallow, the botanist and chemist at the station, has issued no less than four reports last year and this. These deal respectively with the meteorology of the district in which the farm is situated, based on observations extending over a period of six consecutive months; with soil temperatures, a series of observations embracing a similar period; with the normal condition of vegetable structure with reference to cell contents; and with "peach yellows," a disease attacking peach trees. To do justice to any one of these memoirs would really require a separate notice, but the mere mention of them will serve to indicate some of the channels into which the energies of this new centre of research are being directed. In connection with the meteorological work, however, it is worth noting that daily bulletins were issued, the predictions being made for twenty-four hours from noon to noon. The whole number of predictions made was 210, of which only 1·9 per cent. proved incorrect, so that the bulletins came to be depended upon and served a most important purpose for the time during which they were issued. All the reports are printed in an attractive form, and special pains appear to have been bestowed upon the diagrams and coloured plates.

To the names that have already been mentioned it is necessary to add that of Mr. Henry E. Alvord, who has undertaken the duties of general manager. Mr. Alvord's name is already familiar to agriculturists on this side of the Atlantic, particularly in connection with American dairy farming, and his association with Houghton Farm is another guarantee, if one were needed, of the thoroughly business-like manner in which the new experiment station is to be conducted.

From this brief sketch it will be seen that there exist at Houghton Farm potentialities whose development can hardly fail to exercise considerable influence on the agricultural practice of the future. Those who have studied the Rothamsted results will be glad to compare with them the results deduced from the Houghton Farm experiments, and each station will be benefited by comparing notes with its friendly rival, while the valuable work which English agriculturists associate with the names of Lawes, Gilbert, Pugh, Masters, and Warington will, it is to be hoped, find a parallel in the discoveries we shall confidently look for from the transatlantic station. Intentionally planned, in many details, upon the same lines as Rothamsted, there is one point in which the new station specially resembles its English prototype, and it is contained in the words, "Visitors are always welcome at Houghton Farm." W. FREAM

EDELMANN'S ELECTROMETER

AMONGST the many forms of electrometer that derive their origin from the quadrant electrometer of Sir William Thomson is that of Edelmann, which is very extensively used in the physical laboratories of the Continent. Dr. Edelmann, whose name it bears, is not only proprietor of workshops in Munich, which are rapidly winning renown for the excellence of the instruments which they turn out, but also holds the post of *privat-docent* in the Polytechnicum of Munich.

In the parent instrument of Sir W. Thomson, and in most of the modifications of that instrument which go by the names of Branly, Kirchoff, Mascart, &c., the quadrants are literally four quadrants cut from one plane circle; and in most of these instruments the *needle* is of the flat dumb-bell or lemniscate form which Sir W. Thomson himself gave to it. Dr. Edelmann has, however, taken a departure in quite another line, his instrument being very appropriately named the "cylinder-quadrant" electrometer. The three accompanying figures show the essential parts of the instrument. The quadrants, marked G in Fig. 1, and *a*, *b*, *c*, *d* in Fig. 2, are formed by taking a metal tube, furnished with flanges above and below, and slitting it into four parts by four equidistant cuts parallel to the axis of the tube; the four pieces being then set in their proper places by being screwed to two rings, R and S, of ebonite. This arrangement has some advantages over those of the ordinary quadrant electrometers. In these, when the quadrants consist of four pieces of flat brass borne each on an insulating pillar, it is difficult to set them so that they shall be all exactly in one plane; and when, as in some of the more delicate instruments, the quadrants are made of a hollow box slit into four parts, there is found the further difficulty of arranging the quadrants so that the needle can be taken out and replaced. These difficulties are, to a large extent, obviated in Dr. Edelmann's form of instrument; for the inner surface of the cylinder, which constitutes the four quadrants, can be turned perfectly true after the quadrants have been screwed to the ebonite rings; and there is no difficulty at all in lowering the needle into the cylindrical cavity within the quadrants, or in lifting it out. The needle itself is of the form shown in Figs. 2 and 3, and consists of two portions of metal (W W) cut from a cylinder, united above and below, and hung by a single fibre of small torsion from an adjustable head, F, above. A mirror, *s*, is attached above the needle, and a platinum vane, P, below it dips into a vessel, T, containing sulphuric acid. To give directive force to the "needle" a small magnetic needle, *n s*, is attached to it. This device was indeed used in some of Sir W. Thomson's early instruments, though subsequently abandoned in favour of the bifilar suspension usually adopted. It is of course understood that the opposite pairs of quadrants are, as usual, connected together. Electrodes, A, B, pass through the metal plate, M, which covers the instrument, and are connected with the quadrants as shown in Fig. 1. An outer jar of glass surrounds the instrument and is fixed to the under side of the plate M by a bayonet point. The plate M itself is very substantial, and is provided with three levelling screws which rest in V-grooves in a strong ring-

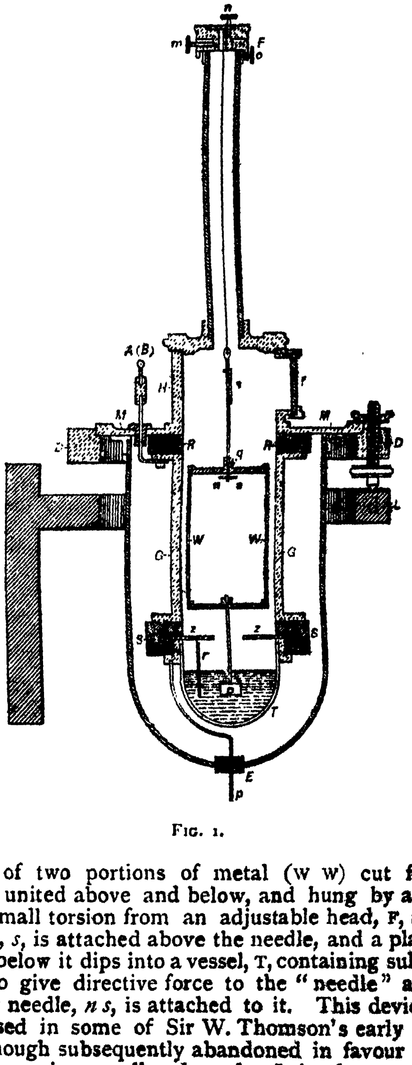

FIG. 1.

shaped support of cast zinc, L L, which is screwed to the laboratory wall like a bracket.

It will be seen that Dr. Edelmann has discarded the Leyden jar, replenisher, and gauge, which play so important a part in Sir W. Thomson's electrometers. Instead of these a Zamboni pile, or a battery of 200 small well insulated voltaic elements, is used. These are made of test-tubes filled with common water, and having small zinc-copper pairs placed from cell to cell. It is difficult to believe that either of these dispositions is an improvement on the replenisher-jar-gauge arrangement, though either may be somewhat cheaper. Nor is it likely that the presence of the ebonite rings R and S will add, in the long run, to the satisfactory working of the instrument; for, as is well known, this substance when exposed to light decomposes at the surface, and becomes covered with a conducting-film of acid. The insulation of the quadrants ought not to be risked by such a doubtful device. It ought to be mentioned that a cylindrical arrangement of quadrants had been previously employed by Silow in an instrument for investigating the dielectric capacity of liquids: but to Dr. Edelmann is due the credit of having applied this arrangement for the construction of these electrometers, which in consequence of their many good points are becoming so popular for laboratory work both in Germany and elsewhere.

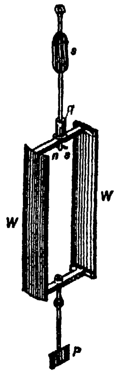

FIG. 3.

GLEANINGS FROM THE REPORTS CONCERNING THE ERUPTION OF KRAKATOA

I DO not propose to give here an abstract of all the reports which I have gathered, but I only wish to state some important data which might be useful to those who wish to become acquainted with the full particulars concerning the eruption. Therefore I have mentioned the authorities from which I have taken the following statements, in order that the reader who wishes for more circumstantial reports may find them easily.

I regret to say that I have not been able to find any reports from Tjiringin and the lighthouse-keepers of Java's First Point and Vlakke Hoek. In the beginning of October an engineer of the mine-service was sent to Krakatoa to examine the island, and he is expected now to bring in a scientific report about the eruption; it is to be hoped he has insisted that everything referring to the catastrophe should be circumstantially recorded.

1. *Data referring to the time anterior to the Eruption.*—In a report which was published in the *Java Courant* (the paper of the Dutch Government), which was brought from Batavia by the mail of August 25, it was said: "There are now two craters on Krakatoa, 3 km. distant from each other, which are continually working. The western crater is at the foot of Mount Perbuatan (working since May 20); the eastern crater working since a more recent date (which is unknown to me) at the foot of Mount Dannan. The outlines of the top of Mount Perbuatan are changed; the outlines of the beach are also altered by some increase of land along the shore. The trees which covered the island are burnt for the greater part."

As to what occurred before and during the eruption of August 26 and 27 I particularly took the data:—

(1) From the report of the *Berbice*, Capt. Logan, from New York (*Nieuws van den Dag*, October 11): August 26 at 2 p.m. she was off Vlakke Hoek, 20 miles to the south; she got sight of the light of Java's First Point August 28 at 12 p.m. Since August 26 at 4 p.m. she had only little sail; 28, at 4 a.m., maintopsail was set; afterwards at noon she set full sail and made for First Point. Therefore she was during the eruption near a line which joins Java Head and the point where she was August 26 at 2 p.m.

(2) From the report of the *Charles Bal* (NATURE, Dec. 6, p. 140): She passed Prince's Island August 26, at 9 a.m.; Krakatoa seen at 4.15 p.m., north half east, 10 miles distant. At 11 p.m. the island became more visible, west-north-west, 11 miles distant; August 27 at 6 a.m. she set sail, passed lighthouse Fourth Point at 8 o'clock, Anjer at 8.30; passed Button Island at 10.15.

(3) From the report of eye-witnesses, who were at Anjer during the catastrophe (*Nieuws van den Dag*, October 11 and 14).

(4) From a report written by a passenger (an engineer) of the *Gouverneur Loudon* (Dutch Indian steamer, 761 reg. tons, 190 h.p.) (*Nieuw. Rotterdam. Court.*, October 23, by Mr. van Sandick): She was off Anjer August 26 at 3 p.m.; went to Telok Betong, where she arrived at 7 p.m.; remained there till next morning at 7 o'clock. After a wave had destroyed Telok Betong she made for Anjer, but before she had left the bay darkness came on, and she was compelled to lie there till August 28 in the morning.

(5) From the report of eye-witnesses at Telok Betong (*Nieuws van den Dag*, November 3 and 13).

Moreover, I took a few particulars from the reports of Katimbang (*Nieuws van den Dag*, October 16) (Lampongs, at the foot of the Radjah Bassa), Binuangan (*Nieuw. Rotterdam. Court.*, October 23) (at the bottom of the Semangka Bay), and Pulu Merak (*Nieuws van den Dag*, October 10).

Though *e.g.* on the Island Bali strong detonations were heard in the morning of August 26, the reports of Telok Betong and Anjer say: Fine weather, no extraordinary detonations in the afternoon. *Berbice* reports: Sky dark at 2 o'clock, threatening at 4 o'clock; at 6 p.m. thunder and lightning. On board the *Charles Bal* at 4.15 an eruption at the east of Krakatoa was observed; the masses which were driven forth to the east had the appearance of a furious squall. Anjer reported: At 6 o'clock quite dark; at Telok Betong at 6 p.m. slight rain of ashes; at the same time *Berbice* experienced ashes pouring down at once; it was quite dark. Fall of ashes and darkness continued the whole evening. About this time the commotion of the sea began also. At Anjer, between 6 and 7 p.m., several vessels were carried by the wave to and fro in the harbour (canal), but the sea did not flow over. From Merak is reported, August 26, at 7 p.m. or 7.30 p.m.: Heavy detonations, violent shocks (but no earthquake). Waves swept away the Chinese camp; caused much damage. In the night (I could not find out at what o'clock) fiery phenomena were seen in the direction of Krakatoa, shocks of earthquake, waves. The Controleur, who was at Katimbang, related: "August 26, 7 p.m., several prows thrown on the beach, waves, but the sea did not flow over, nor did the waves grow higher."

The *Loudon* came to anchor off Telok Betong at 7 p.m. Rough sea, boats could not communicate. They observed that there was something wrong, but could not make out what it was. The Dutch bark *Marie*, which was there also (there are two vessels of the same name, *Marie* and *Maria*, in the list, the one, *Marie*, of 570, the other, *Maria*, of 790 tons) reported: At 7.30 currents observed in different directions, some small vessels lost their anchors, ten persons saved from being drowned. From Telok Betong is reported: By 6.30 sea quite calm, level of the sea 1 metre lower than pier, a moment afterwards 1 metre above it; people who were at the end of the pier, about 1000 metres distant from the shore, had to walk back through the water, which was done without accidents. Meanwhile the *Charles Bal* was in a fearful situation since 5 o'clock. She reports:—"At 5 p.m. sky darkening, detonations stronger, pumice-stones pouring down, rather big pieces, had to cover skylights. At 6 p.m. big pieces ceased, small pieces, ashes, &c., continued. Terrible night. After 7 p.m., at Anjer, heavy detonations were heard, the ground was groaning, thunderstorm; by 9.30 calm, slight rain of ashes. After this the sea was very calm. After midnight some waves were observed, which were not violent. Lloyd's agent at Batavia wrote under date of October 16 (*Scotsman*, November 24):—"But we know now that the village of Sirah, six miles below Anjer, was partially submerged at 1 o'clock on Sunday night, August 26. This I had from the head man himself, who at the time reported it at once. . . . At Anjer, however, nothing was felt and no alarm was experienced." At Katimbang a noise was heard of a far-off wave at 10 o'clock, and the Europeans and natives went to a higher place. During the night the waves were heard causing an awful devastation. At Telok Betong, by 10 o'clock, several vessels were thrown on the beach (among which the steamer *Berouw*, draft 1·75 m., 4 guns, 30 h.p., 4 Europeans, 24 natives), houses swept away, people drowned, &c.; towards midnight calm.

From this it seems to me that no extraordinary detonations were heard nor any phenomena seen which could have startled the inhabitants, who, however, had been accustomed for three months to the noise of Krakatoa.

Meanwhile the outburst continued. The *Berbice* reported:—At midnight ashes increased, pieces of pumice-stones, thunder and lightning increased, fireballs fell on deck and were scattered about, fearful roaring, copper at the helm got hot; helmsman, captain, and several sailors were struck by electric discharges; sail over the hatches to prevent fire, helm tied, crew sent below, captain and master kept guard; 27th, at 2 a.m, all hands to shovel ashes into the sea (were about 3 feet thick lying on deck). In a still worse situation was the *Charles Bal*. Lightning continued; saw a light at 11 p.m., supposed it to be the light of the Fourth Point (Anjer lighthouse); lay by; Krakatoa visible in west-north-west, 11 miles distant; wind strong south-west, chains of fire appearing to descend and ascend between the sky and the island, while on the south-west end there seemed to be a continued roll of balls of white fire; the wind, though strong, was hot and choking, sulphurous, with a smell as of burning cinders, some of the pieces falling on us being like iron cinders, and the lead from a bottom of 30 fathoms came up quite warm. From midnight to 4 a.m. (27th) wind strong, but very unsteady between south-south-west and west-south-west, impenetrable darkness continuing, the roaring of Krakatoa less continuous, but more explosive in sound, the sky one second intense blackness, and the next a blaze of fire; masthead and yardarms studded with corposants, and a peculiarly pinkish flame coming from the clouds, which seemed to touch the mastheads and yardarms."

On the morning of August 27, by 6 o'clock, as is reported from Binuangan (Semangka Bay), the sunken cliffs were visible; a little while afterwards a wave came and returned, but another followed, which did much damage; soon (?) after this it became quite dark, mud and ashes poured down; several waves followed till late in the evening; darkness continued till next morning. From Anjer is reported that it was about 6 o'clock when the first wave came. One of the persons who were saved said: "I went out about 5.15. After having talked with several persons, I saw the wave, still far off, rapidly making way towards us. I ran away, was followed by the wave, fell down quite exhausted, but happily on a hill, where the water could not reach me. Before my eyes all the houses along the beach were destroyed." Another person reported:—"I was early at the beach (early, after Indian habit, might be at 5 o'clock). When I returned home I heard a cry, 'The flood comes.' On looking round I saw a high wave which I could not escape; I was lifted from the ground, but caught hold of a tree. Then I perceived several waves, which followed the first; the place where Anjer had been before was covered by a turbulent sea, from which some trees and roofs of houses were still peeping out. After the wave had flowed off, I left the tree, and found myself in the midst of the devastation. The Chinese camp was not yet destroyed." A third person, who was still in bed at 6 o'clock, was lifted up by the wave and carried to a hill. All agree that after 9 a.m. it became dark, and a pouring down of mud and ashes commenced (darkness till next morning), &c. From Merak it is reported that in the morning all European officers were in their houses; when the first wave came they were not afraid, and would not yet go to the hills. The *Berbice* reported: "Till 8 o'clock it was, as before, quite dark, afterwards worse." The *Charles Bal*: "August 27, 6 a.m, being able to make out the Java shore, set sail. Passing Fourth Point Lighthouse at 8, hoisted our signal letters, but got no answer. Passed Anjer at 8.30, name still hoisted, close enough in to make out the houses, but could see no movement of any kind; in fact through the whole straits we have not seen a single moving thing of any kind on sea or land."

I must confess I am here at a loss. It is possible that the *Charles Bal* passed Anjer after the first wave had annihilated most of the living beings and before the following waves had finished the destruction of buildings, though it would be strange if at the lighthouse all the people had been killed before the building was destroyed. Moreover, it seems strange to me that the captain should not have seen the devastation nor remarked the tidal waves When they came on, the ship was very near them, and even if we suppose that the waves had been shot like a projectile from Krakatoa on to Anjer, it would be astonishing that such a considerable mass of water should not at all have been perceived, or not described if it had been. We learn from Anjer (and from Telok Betong) that it was seen from the beach like a black wall, and it must have had a considerable height, for it covered all the houses and trees which were near the beach; now an ordinary house might at least be ten or twelve metres high, and the shaft of a cocoanut tree has also a considerable length. *Loudon* reports: August 27, in the morning fine weather, at 7 a.m. an immense wave came on; the *Loudon*, under steam, turned her head to it, was lifted up, but kept well; now the wave rushed on to the beach, and before the eyes of the passengers and crew of the *Loudon*, houses disappeared; the *Berouw* (which had been thrown on the beach on the evening of the 26th) was lifted up and carried a few kilometres into the land. The place where Telok Betong had been before was changed into a violent sea (except the buildings on the hills). Three other waves followed at short intervals. Since it was supposed that the cable had been destroyed, the steamer intended to go to Anjer to report the catastrophe. Before she could get out of the Lampong Bay it darkened. The mate of the *Marie* reports: August 27, in the morning the sea was calmer, but queer weather, sky threatening, prepared the third anchor. At once we saw an immense wave at the horizon making rapidly its way on to us; we spiked up the hatches, and after having done it the first wave struck the vessel, and threw it on the beach; after the wave had flowed off, the *Marie* was literally on dry sand; one could have walked around the vessel. Part of the crew left the ship. From the barracks at Telok Betong, on the Talang Hill, about twenty-five metres above the level of the sea, an eye-witness wrote: At 6.20 I went to Kampong (village) Kankong, about 1400 metres distant from the barracks, to see the destruction which the wave had caused the night before. After I was there I saw a wave rushing on to us; we hastened to the hills, the villagers following us. When I had reached the barracks, I saw Kampong Kankong had disappeared, and so had the other villages near the beach. Before the darkness began the water rose. At Katimbang they perceived in the morning what damage had been done—by little and little it became dark.

At 10 o'clock it was so dark aboard the *Loudon* that not even outlines of the ship or persons were visible; she stopped for eighteen hours. Rain of mud covered the deck 0·50 metre thick. Needle of the compass violently agitated; barometer extremely high; breathing difficult through damp; some people got unwell and sleepy. After the darkness began the sea became violent, the wind increased; at last it was a hurricane. Then several heavy seas came, some of which came across and almost capsized the vessel. The flash of lightning struck the *Loudon* seven times, went along the conductor, but, when still above the deck, sprang over into the sea. This was accompanied by a dreadful crackling. At such moments the vessel and the surroundings were brightly lighted; it was a fearful sight, everything being covered with a grayish mud. During all this time the *Loudon* was under steam, steaming slowly at two anchors. St. Elmo's fires at the masts and yards. August 28, at 4 a.m., feeble moonlight (moon's rise at Batavia, August 28, at 2.15 a.m.) at the horizon. After the sun had come up she tried to leave the bay. It seems worth attention that during all these fearful hours no detonations were heard aboard the *Loudon* (this is expressly mentioned in the report).

At Merak an immense wave came by 9 o'clock from the west and rushed to the east. The European who alone escaped went to the hills, while darkness surrounded him. The mate of the *Marie* writes:—By 10 a.m. (August 27) three heavy seas came after each other; quite dark; at once a fearful detonation. Sky in fire, damp. By 3 p.m. three seas again, after this the sea quite calm. Dark till next morning, then (28th) *Marie* was found afloat again. From the barracks (Telok Betong) it is reported:—By 9.30 a.m. a downpour of ashes, later stones and mud; about half an hour afterwards the level of the water was only 1 or 2 metres below the top of the hill. Now it was taken into consideration to give up the barracks and retire to a higher point. In the night the rain of mud ceased by little and little, the sky cleared up, stars appeared. When, at Katimbang, it had become quite dark, fearful detonations, like thunder and reports of guns, were heard. By 11.30 pouring down of stones began (the biggest as large as a fist). Half an hour after, 12 o'clock, it became quite dark; heavy rain of ashes soon afterwards, hot ashes (during a quarter of an hour), then cold ashes; darkness continued (it is not said when it dawned). From the *Charles Bal* is reported: "At 11.15 there was a dreadful explosion in the direction of Krakatoa, now over thirty miles distant. We saw a wave rush right on to the Button Island, apparently sweeping right over the south part, and rising half way up to the north and east sides. This we saw repeated twice, but the helmsman says he saw it once before. The same wave seemed also to run right on to the Java shore. At the same time the sky rapidly covered in, the wind strong from south-west by south; by 11.30 we were inclosed in a darkness that might almost be felt, and at the same time commenced a downpour of mud and sand, &c., which put out the side lights. At noon the darkness was so intense that we had to grope our way about the decks, and although speaking to each other on the poop, yet could not see each other. This horrible state and downpour continued till 1.30, the roarings of the volcano and lightnings being something fearful. By 2 p.m. we could see some of the yards aloft, and the fall of mud ceased. (Here the explosion and the beginning of the darkness are reported about two hours later than from Lampong Bay or from Anjer, and still more astonishing is it that nothing is said about the wave which annihilated Merak). At 5 p.m. the sky cleared up in the north-east, but till midnight sky dark, now and then ashes falling. Though the vessel was sixty-five to seventy miles distant from Krakatoa, the roaring of the volcano was still audible." From the *Berbice* is reported: At 11 a.m. (27th) strong wind south-east; at 3 p.m. high wave (about 20 feet high) struck the vessel so hard that the chronometers were arrested. Thunder, &c., continued, and the hands of the barometers were violently agitated between 28 and 30 inches. At 6 p.m. no change, sea relatively calm, lightning allowed us to see the vessel surrounded by a sea of pumice-stone; at midnight, weather calm, lightning more remote. August 28, at 4 a.m., calm, maintopsail set. Darkness continued. At 8 a.m. they saw daylight again. Weather calm and bright. Ship covered with ashes about 8 inches thick. During the eruption about 40 tons of ashes were thrown overboard; more sail set; had full sail at 12 o'clock, and went straight on to Java Head. Floating pumice-stone diminished the speed of the vessel. At midnight light of First Point was seen; when they passed Prince's Island they saw banks of pumice-stone 18 to 24 inches thick. In the afternoon they passed between Krakatoa and the Java shore. As far as they could see the island was by two gaps divided into three parts. The sea was covered with pumice-stones and floating corpses.

I continue the report of the *Loudon*:—Ashes and pumice-stone were still falling, but only slightly; the vessel was near the shore; it was a dreadful sight, trees buried under ashes and mud, the sea covered with pumice-stone and driftwood. Near Pulutiga the entrance of the bay was obstructed by islands of pumice-stone, like cliffs; they formed a bridge between Pulutiga, Sebuku, and the mainland. Since the channel of Lagundi Straits seemed comparatively open, the *Loudon* made for it, but she met there with an island of pumice-stone, about 3 m. thick; she went ahead against it, the pumice-stone gave way, and though there were some difficulties at the pumps, the *Loudon* got free; now it was resolved to go to Anjer, the vessel came to the Sunda Straits, west (in the report is said east, which seems a slip to me), then south of Krakatoa; when this island was at larboard (I think it means when the *Loudon* went to the north, passing between Krakatoa and the Java shore, for after having left the Lagundi Straits, she continually had Krakatoa on the larboard) it was seen that the greater part of the island had disappeared; there was a steep crater-wall, the peak as it were cut into two. In the wall large cracks filled with smoke were remarked. In the sea between Krakatoa and Sibessie several volcanic reefs were seen, there, as it seemed, volcanic powers were still at work. At eight different places columns arose, which, after having originated in a dark point, grew larger, got as it were a white bordering, arose to a considerable height, and gave way to another column. It could not be made out whether these phenomena were waterspouts or volcanic eruptions.

It is known that the detonations were heard all over the Dutch colonies and further; I only beg to record that at Acheen, 5½° N. lat., they were so distinctly heard that military forces were sent out, since it was supposed that a fort had been attacked. It may be interesting to see a report from Padang Panjang, which runs as follows: August 27, 8.30 a.m., at once a heavy explosion, a single thick cloud of smoke arose (from Mount Merapi 0° 20′ S. lat., 100° 28′ E. long. Greenwich) drove directly away; now smoke arose from a point at some distance from the crater, uncertain whether it originated in ejected matters, or whether there were fumaroles. After five minutes the same phenomena were observed; afterwards it was perfectly quiet. At 10.50 a.m. hollow groaning; another column of smoke arose; ashes falling eastward; two columns of smoke. During all this time a fearful noise was heard from afar, which became stronger after 11 a.m.

Dr. B. Hagen wrote to the editor of the *Ausland* (*Ausland*, No. 46) from Tandjong Morawa (Deli, Sumatra, almost 1000 km. distant from Krakatoa): In the afternoon (27th) thick white clouds were seen coming from the volcano Sipaiak (or Guming Balerang), more than 30 km. distant to south-west.

From Menggala (130 km. from Telok Betong to the north-west) is reported: Slight concussion of the air, rain of ashes, darkness. From Sukadana (105 km. from Telok Betong to the north-east) is reported: Much damage done by falling ashes and stones.

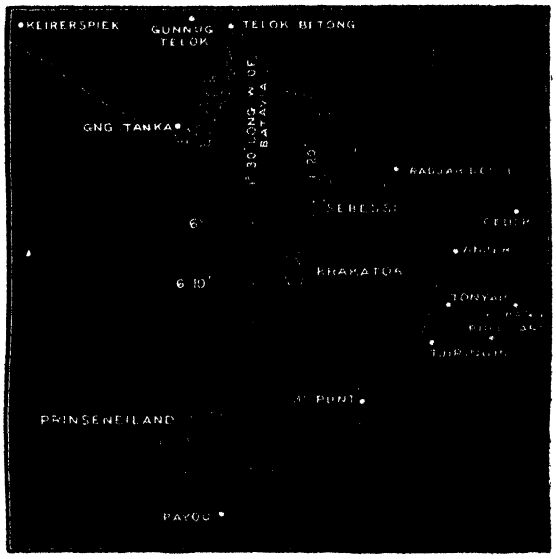
During the eruption there were still two vessels near the Sunda Straits the reports of which are to be mentioned. The *Annesley* (*Times*, weekly edition, Oct. 12), Capt. Strachan, from Singapore, August 27, for Mauritius: At 10 a.m. it was so dark that they had to light all the lights. Barometer rising and falling ½ inch to 1 inch in the minute. Ashes and pumice-stones falling. Towards the night ashes stopped, but it was as black as night. August 28, they passed the Sunda Straits, and heard from the lighthouse-keeper (Java's First Point) that he had had fearful weather. Had some of the ashes as far as 100 miles clear of Java Head.

The hopper-barge *Tegal* made from Batavia for Merak, August 27, early in the morning. On the way they met with ashes and stones pouring down; it became quite dark, sea rough; came to anchor by 12 o'clock; dreadful weather; she dragged her anchor. Towards 3 o'clock the sky cleared up, then went on till 5 p.m. In the night they saw a bright light in the south and west, many flashes of lightning, and balls of fire; several sea-quakes; at once sea like glass. In the morning (August 28), when it dawned, the *Tegal* was off St. Nicholas Point; now she entered the straits; they saw the devastation. At Dwars-in-den-Weg the sea had still deepened the deep places which were there before; Saleier and Tempora had disappeared; the height of the waves at Merak was estimated from 30 m. to 40 m. by the chief of the works at Merak (*Nieuws van den Dag*, October 10).

The *Prins Hendrik*, a Dutch man-of-war (2000 tons, 400 h.p., 5·5 m. draft, 8 guns, 229 Europeans, 53 natives) was sent to the Sunda Straits for the safety of the vessels arriving there (*Nieuws van den Dag*, November 17). She first went to Vlakke Hoek, but could not communicate on account of the pumice-stone; another vessel succeeded in communicating (September 3), and found of the men of the lighthouse (5 Europeans, 14 coolies) 10 natives dead, 3 Europeans and 4 natives wounded. The base of the lighthouse is 2·5 m. above the level of the sea; the first (iron) floor was broken, the lodgings near the lighthouse swept away. The *Hendrik* observed that the north part of Krakatoa had disappeared; from the part which remained, from Verlaten and Lang Island, and the new ones (Calmeyer and Seers), smoke continually arose; now and then, by night, a flame was seen. September 16, the *Hendrik* tried to enter Semungka Bay. They found a place where the sea was not covered with pumice-stone, but landing was impossible, the breakers being too strong; next day a boat was sent again, which was beset in the floating masses. The pumice-stone around the *Hendrik* was now 5 feet thick, and one could stand on it. The boat had at last to be given up, the crew (being one lieutenant, Dutch Navy, two boatswains, fourteen sailors) went on shore. The *Hendrik* tried to leave the bay, but could hardly turn round; a condenser exploded, and they had to come to anchor. As far as they could see, the sea was covered with pumice-stone. After thirty hours the engine had been repaired and cleared, and after much trouble the steamer got out of the bay.

Though the reports which I have mentioned are far from being complete (I shall try to complete them), I think they are sufficient to draw some conclusions:—

1. As to the height of the wave, we have seen that the first waves at Anjer were more than 10 metres high (August 27, 6 a.m.). At Merak the height of the most destructive wave (by 9 o'clock) is estimated at 30–40 metres by the engineer himself, and Mr. McColl (the *Scotsman*, November 24) estimated it to be 135 feet (about 41 metres). At Telok Betong (Talang hills) it was about 23 or 24 metres, but here it was not properly speaking a wave, but it seems that the water in Lampong Bay was dammed up as it were. I suppose that the bay by the first waves was filled, and the mass of water broke here the force of the explosion, and the wave by which the latter was followed was turned to the east (from Merak the wave came from west). In general I do not suppose that we may speak about "waves" in the ordinary sense. Besides the previous commotions, which were of course very strong, I suppose that by the explosion (let us say August 27, 9.30) an immense mass of water was driven to the north, and escaped as far as it could into the Java Sea; probably other concussions followed, and afterwards the mass flew back (this was the wave the *Berbice* met with at 3 o'clock), and went into the Indian Ocean. If this supposition be true, I think Vlakke Hoek lighthouse was also struck by the wave in the afternoon (which, of course, I do not know). That the water was really dammed up, we learn also—though the effect was not so strong—from the report from Telok Betong about August 26. The men, being on the pier, had to make their way home through the water, which at the time was rather high, and they could never have done it if there had at that moment been a flowing off of the wave. From different reports it results that the waves produced their effect in a certain direction, and not around (*e.g.* destruction in the night 26th to 27th, Sirah, south of Anjer; 26th, in the evening, destruction at Merak, only slight commotion at Anjer).



2. The barometer. From the *Berbice* it is reported: 28 to 30 inches, violently agitated. *Annesley*: rising

and falling ½ to 1 inch in half an hour. *Prinses Wilhelmina* at Tandjong Priok: 789–763mm. (*Nieuw. Rotterd.* Nov. 26) (789 seems a misprint, *Nieuws van den Dag* has 750, perhaps it should be 759). *Loudon*: extremely high.

3. Compasses. Spun round (*Loudon*).

4. Degree of darkness. From all reports results that there was a moment when "no outlines of ship or men were seen." From the report of the *Annesley* results that the darkness continued after the downpour of ashes had ceased, therefore the darkness is not depending on the pouring down of ashes; it is sufficient that the sunlight be intercepted by a thick cloud of ashes. From the *Berbice* is reported:—Darkness from 26th, p.m., to 28th, a.m. From all other places is reported:—Bright, August 27, from 6 to 9 a.m., and 28th, from 6 a.m.

5. After having read the reports, the question arose to me, Was the mud ejected from the crater, or were the ashes, &c., mixed with rain or sea water? I think the latter; I remember, at least, that in 1863 (an eruption of the Merapi, Java, took place) I came into a slight downpour of ashes. I was travelling on horseback, and after some time a thunderstorm came on. All around me, which had been ashes before, was changed very soon into mud. In the report of the *Berbice* the "rain of mud" is not mentioned, but it is said that the yards were covered with a "crust," because a slight rain had met the ashes, which, however, on deck were still "ashes," because, I suppose, the rain was not hard enough to change such a thick layer into a "crust."

6. Detonations, though they were heard in Saigon, Singapore, Acheen, Ceylon, &c., were not heard on board the *Loudon*. I think this might be explained by the thunderstorm, the pouring down of mud into the sea, and the hurricane (which in Lampong Bay did more damage than the wave itself).

7. The part of Krakatoa which has disappeared sank probably August 27; at least in the report from the *Loudon* the island is described as it is now. From the *Berbice*, however, it is reported:—Saw it divided in three parts (29th); but probably they saw the remains of Krakatoa, Verlaten Island, and Lang Island, which before, when seen from the east, appeared as one island.

8. Sibessie was from the sea to the top buried under ashes (all people killed).

9. The floating pumice-stone was, in the Lampong Bay, in September, 14 feet thick; in the Semungka Bay it was very strong too. Probably, if circumstances are favourable, new islands are to be formed; though at the end of October steamers came to Telok Betong, in November a hopper-barge was, during eleven days in the Lampong Bay, beset by pumice-stone.

Besides this I beg to record:—

10. After the eruption of Krakatoa in the Indies many volcanic phenomena were observed, and they prophesied an eruption of Mount Merapi (Java) for February next. Whether they had heard of Mr. Delaunay's prophecies I am unacquainted with.

11. Up to November 1 they counted 32,635 persons killed by the eruption, &c. For the burial of the corpses the Government had spent 6000*l.*

When the Survey under my direction (1868–69) was busy connecting the triangles of Java with the Sumatra coast, the peak of Krakatoa was also chosen for a point.

Whether there were several hills on the island I cannot say, for when I saw Krakatoa it was covered with a splendid vegetation, and in such a case it is not so easy to judge of the configuration as it is when the trees are burnt, but I dare say there was only one peak.

Of the results of the Survey I keep only a map, of which I inclose a rough copy. From this it results that the signal was a little to the north of 6° 8½′; Kuyper puts it in 6° 9′, which is certainly wrong; he inserts also a peak in the centre of the island (622 metres), and says it had disappeared; this is, I am sure, a mistake. If the military survey (which was at work now) had not yet finished its work so far as to give a map of Krakatoa (though perhaps they have not undertaken a survey of the island, since administratively it belongs to the Lampongs, and not to Bantam), it might perhaps be useful to consult the notes of the *Geographische Dienst*, which are deposited in the Archives, and a sketch of the Sunda Straits, which I offered in 1875 to the Minister of the Dutch colonies.

E. METZGER

Stuttgart, January

NOTES

WE regret to learn that Mr. C. W. Merrifield died at Brighton on New Year's Day at the age of fifty-six.

MANY of the friends of the late Dr. Hermann Müller in this country will be glad of the opportunity of testifying to their respect for his memory and their sense of the value of his work by contributing to the fund which is being raised to establish a "Müller Foundation." In the first instance the proceeds will be used to assist the widow of Dr. Müller during her lifetime, and afterwards as an endowment to some poor and deserving student at the Public School of Lippstadt desirous of devoting himself to natural science. An influential Committee has already been appointed on the Continent, including the name of Prof. Haeckel. The movement, we are sure, will commend itself to many of our readers, who may send their subscriptions either to Herr Stadtkaemmerer Wilhelm Thurmann, Lippstadt, or to the care of the Editor of NATURE.

FIVE HUNDRED POUNDS in prizes are offered by Mr. Francis Galton for extracts from the family records of competitors. They are to be sent him before May 15, drawn up according to the conditions and under the restrictions published in his recent book, "Record of Family Faculties" (Macmillan and Co., 2*s.* 6*d.*), which contains full explanations, together with sufficient blank forms for the records of a single family.

M. BOULEY has almost unanimously been appointed Vice-President of the Paris Academy of Sciences for 1884, and President for 1885.

EARTH tremors seem to have been of almost daily occurrence in Tasmania recently. Mr. J. R. Hurst of Longwood, near Moorina in the north-east of the colony, sends to the *Launceston Examiner* of November 12 a record extending from August 31 to October 20, 1883, noting the occurrence of several daily, some of them so serious as to be alarming. In a note in its issue of November 19 the *Examiner* says:—"The vibratory motions of the earth's surface which have been so frequent for several months past still continue with a periodicity which is at least remarkable. Ordinary tremors now scarcely arrest attention, but occasionally a quivering of unusual severity startles those who happen to notice it, and reminds them that there are forces in operation in nature which are mysterious and appalling. One of these occurred yesterday afternoon about six minutes to three o'clock, which was felt in every part of the town, and set windows and furniture rattling. Some persons fancied that they could detect a distinct undulatory motion. The shock lasted for twelve or fifteen seconds. It may be mentioned that the whole of yesterday was very stormy—frequent and heavy showers of rain, with thunder and hail, and a very low barometer. Last evening the mercury began to rise."

PROF. J. P. LICHERDOPOL writes from Bucharest, Roumania, that on January 1, at 6.13 a.m., two horizontal shocks of earthquake, from north to south and *vice versâ*, were felt there, and were preceded by a loud noise, as of a distant train coming from the north. The furniture was slightly shaken and crackings were heard. The atmosphere was calm, but charged with a very thick and persistent fog.—Earthquake shocks were also felt during Sunday week in various parts of France. At Argèles (Hautes Pyrénées) there was one in the early morning, a second at nine o'clock, and a third about mid-day. At Dorignies, an industrial hamlet near Douai (Nord), the shock was sufficiently strong to cause real alarm. It occurred between six and seven in the evening. Houses shook, their timbers cracked, and glass and earthenware in cupboards were shattered.

THE Hungarian astronomer, Herr von Konkoly, who is mentioned as the future director of the Brussels Observatory, is exexpected to arrive there in about a week, for the purpose of explaining to the Science Department of the Belgian Academy his recent discovery relative to the cometary spectrum.

WE understand that Messrs. McLachlan and Fitch, having been appointed by the Entomological Society of London a committee for the purpose of examining, and reporting upon, certain vine-roots forwarded by the Government of Victoria, through Kew, find as the result of their examination that the *Phylloxera* is present in considerable numbers on the roots, which were those remaining in the ground after the vines themselves had been destroyed.
